

Mini-USAGE: reducing barriers to entry in dynamic CGE modelling

by

Peter B. Dixon and Maureen T. Rimmer*

Centre of Policy Studies, Monash University

Paper prepared for the 8th Annual Conference on Global Economic Analysis

Lübeck, Germany

June 9 – 11, 2005

Revised May 23, 2005

1. Introduction

USAGE (U.S. Applied General Equilibrium) is a dynamic computable general equilibrium model of the United States. It is based on the MONASH model of Australia which has been applied widely in forecasting, policy analysis, estimation of technological trends and analysis of historical events. USAGE has many special features and is normally run with about 500 industries.

The detail included in USAGE and earlier MONASH-style models is important for practical, policy-oriented analyses. However, the detail means that comprehensive documentation is necessarily voluminous.¹ While this documentation is essential for keeping track of theoretical and empirical details, it is not ideal for disseminating the principal ideas in the models or the techniques involved in building and applying them.

This paper sets out a miniature version of the USAGE model, Mini-USAGE. Our primary aim in creating Mini-USAGE is to reduce barriers to entry into the world of MONASH-style dynamic, general equilibrium modelling. By providing Mini-USAGE, we hope to give modellers a tool for understanding the theory, construction and computing of

* We thank Laurent Cretegny who encouraged us to build Mini-USAGE. He provided a starting point for our work by implementing in GEMPACK an earlier miniature set out in Dixon and Parmenter (1996).

¹ An annotated version of the complete TABLO code for MONASH is available on the CoPS website at <http://www.monash.edu.au/policy/monbook2.htm>. See also Dixon and Rimmer (2002). A folder of papers documenting USAGE is available from the authors.

MONASH-style models and for interpreting results. For these purposes, Mini-USAGE is unencumbered by detail. We hope that for some modellers, Mini-USAGE will be a useful skeleton onto which they can graft their own detail. A secondary aim of our work on Mini-USAGE is to provide a vehicle for model development. We have found that it is efficient to test and refine new modelling features in Mini-USAGE before embedding them in a full-scale model.

While stripped of detail, Mini-USAGE retains the main theoretical features of USAGE. These include: physical capital accumulation and rate-of-return-sensitive investment; foreign debt accumulation and the balance of payments; public debt accumulation and the public sector deficit; and dynamic adjustment of wage rates in response to gaps between the demand for and supply of labour.

In forming Mini-USAGE, we aggregated the database underlying USAGE from 500 to 5 industries. This allows the miniature database to be set out on a couple of pages and Mini-USAGE simulations to be run in a few seconds. With the miniature data being an aggregated version of the full-dimension data, we find at the macro level that results from Mini-USAGE are a good guide to those obtained from USAGE.

As with full-scale MONASH-style models, Mini-USAGE can be run with 4 basic closures. With these closures, MONASH-style models produce: estimates of changes in technologies and consumer preferences (historical closure); explanations of historical developments such as rapid growth international trade (decomposition closure); forecasts for industries, regions, occupations and households (forecast closure); and projections of the deviations from forecast paths that would be caused by the implementation of proposed policies and by other shocks to the economic environment (policy closure).

The paper is organized as follows. In section 2 we set out the Mini-USAGE database and the computational method. Section 3 describes aspects of the Mini-USAGE theory. Because the *intra*-period equations in Mini-USAGE are quite familiar from earlier models, we concentrate only on *inter*-period or dynamic equations. In section 4 we provide an example of the development role of Mini-USAGE. We describe a problem with Divisia indexes. These indexes are used in MONASH-style models (and are favoured by statistical agencies) for a wide variety of macro variables. However, as we demonstrate, they can lead to distorted results, especially in dynamic policy analysis. We use Mini-USAGE to experiment with alternative indexes. Concluding remarks are in section 5. An annotated version of the TABLO code for Mini-USAGE is presented in the Appendix. This code can be

downloaded from <http://www.monash.edu.au/policy/models.htm> together with data, forecast and policy closures, shock files and instructions for running the model.²

The available version of Mini-USAGE is set up only for year-on-year forecasting and policy analysis. Forecasts can be made as a single sequence of year-on-year solutions (a run of the model). Policy analysis requires two runs: a forecast run and an alternative run that includes the policy shock. Differences between the policy and forecast runs show the effects of the policy. Future downloadable versions of Mini-USAGE will include facilities for running historical and decomposition simulations.

2. Database and computational method

We represent Mini-USAGE and other MONASH-style models as

$$F(V(t)) = 0 \quad , \quad (2.1)$$

where $V(t)$ is a vector of length n referring to prices, quantities and other variables for year t and F is a vector function of length m , $m < n$. The computational approach that we have adopted for MONASH-style models depends on being able to solve the model one period (usually one year) at a time. For year t we specify values for $n-m$ exogenous variables and solve (2.1) for the remaining m endogenous variables. By obtaining a sequence of linked solutions for years τ , $\tau+1$, $\tau+2$, ..., we generate time paths for variables. Links between the annual solutions are provided by lags. For example, we assume that capital stocks at the beginning of year $\tau+1$ (variables in the solution for year $\tau+1$) equal capital stocks at the end of year τ (variables in the solution for year τ).³

Within any sequence of solutions, we obtain the solution for year t [i.e., we solve (2.1)] by the Johansen/Euler⁴ method. This method requires an initial solution, $\bar{V}(t)$, satisfying (2.1). Starting from this initial solution, we obtain the required solution for year t by calculating the effects on endogenous variables of moving the exogenous variables away from their values in the initial solution to their values in the required solution. In most MONASH-style computations, the initial solution for year t is the final solution for year $t-1$

² Mini-USAGE can be run by licenced GEMPACK users of RunDynam or RunMONASH.

³ We may also wish to impose forward links. For example, we may wish to assume that profit expectations held in year τ (variables in the τ solution) depend on profit outcomes in year $\tau+1$ (variables in the $\tau+1$ solution). Forward links pose difficulties for our one-year-at-a-time computational method. These can be tackled by an iterative method, see Dixon and Rimmer (2002, section 21) and Dixon *et al.* (2003).

⁴ So named in recognition of the contributions of Johansen (1960) who applied a version of this method to solve his CGE model of Norway, and Euler, the eighteenth century mathematician who set out the theory of the method as an approach to numerical integration. Early examples of applications of the Johansen/Euler method include Taylor and Black (1974), Staelin (1976), Keller (1980) and Dixon *et al.* (1982). Variants of the Johansen/Euler method underlie the GEMPACK programs [Pearson (1988) and Harrison and Pearson (1996, 2002 and 2005)].

(see Figure 2.1). Thus the computation for year t consists of working out the effects of moving the exogenous variables from their values in year $t-1$ to their values in year t . The initial solution for year 1 comes from input-output data and data on the government accounts, the balance of payments and capital stocks. These data provide a numerical picture (solution) for year 0, which is the initial solution for year 1.

The bulk of the data for Mini-USAGE are set out in Tables 2.1 to 2.4.⁵ These data refer to the U.S. economy in 1998 (year 0). Table 2.1 shows the input-output data, consisting of an absorption matrix and a joint production or make matrix. Tables 2.2, 2.3 and 2.4 contain the government accounts, the current account and the values of capital stocks.

The five industries and commodities in Mini-USAGE are:

1. low-protection goods
2. high-protection goods
3. construction
4. services
5. government

Figure 2.1. A sequence of solutions using the final solution for year $t-1$ as the initial solution for year t

⁵ As can be seen from the Read statements in the TABLO code presented in the Appendix, Mini-USAGE requires some other data items such as starting values for various prices and wage rates. These can usually be set at 1. As well as introducing data items, Read statements are also used to set parameter values, e.g. Armington elasticities.

Table 2.1. Mini-USAGE Input-Output Database for 1998 (\$millions)

As can be seen from the joint production matrix, each industry specializes in the production of the commodity of the same name, but most of the industries can produce more than one commodity. Commodity 4 is used both directly and as a margin service. All commodity flows are valued at basic prices. For domestic commodities this is the price received by the producer (the price at the factory door) and for imports it is the landed-duty-paid price.

By looking at Tables 2.1 to 2.4, we can check various properties of the data including the following:

Sales of good 1 = 3985278 (absorption matrix)

Production of good 1 = 3985278 (joint production matrix)

Direct sales of good 4 plus margin sales = 7130948 + 998549 + 134698 + 1 + 55851 + 0
+ 285565 + 104868 + 0 + 11213 + 0 = 8721693 (absorption matrix)

Production of good 4 = 8721693 (joint production matrix)

Total inputs to industry 1 = 4080705 (absorption matrix)

Total output of industry 1 = 4080705 (joint production matrix)

Government consumption = 1257059 (absorption matrix)

Public consumption = 1257059 (government outlays and revenue table)

Indirect taxes (including import duty) = 20605 + 108835 + 22263 + 0 + 78671 + 0 + 27349
+ 9145 + 0 + 645 + 0 = 267513 (absorption matrix)

Indirect taxes (including import duty) = 267513 (government outlays and revenue table)

Imports (c.i.f. value) = 773473 + 104012 + 0 + 272474 + 0 = 1149959 (absorption matrix)

Imports = 1149959 (calculation of the current account deficit table)

Exports = 966291 (absorption matrix)

Exports = 966291 (calculation of the current account deficit table)

GDP (income) = wages + returns to capital + indirect taxes = 5911380 + 2264647 + 267513
= 8443540 (absorption matrix)

GDP (expenditure) = C + I + G + X - M = 5789259 + (265552 + 13002 + 61950 + 1070687
+ 169699) + 1257059 + 966291 - 1149959 = 8443540 (absorption matrix)

Gross rate of return on capital in industry 1 = $100 \times 444643 / 2495648 = 17.8\%$

Gross rate of return on capital in industry 2 = $100 \times 26160 / 147632 = 17.7\%$

Gross rate of return on capital in industry 3 = $100 \times 55457 / 320379 = 17.3\%$

Gross rate of return on capital in industry 4 = $100 \times 1587960 / 14402637 = 11.0\%$

Gross rate of return on capital in industry 5 = $100 \times 150427 / 3639893 = 4.1\%$

Implied rate of interest on net foreign liabilities = $100 \times 35494 / 1314599 = 2.7\%$

3. Dynamic aspects of Mini-USAGE

Mini-USAGE contains 4 dynamic mechanisms or links between successive years:

(a) capital at the start of year t equals capital at the end of year t-1;

(b) net foreign liabilities at the start of year t equals net foreign liabilities at the end of year t-1;

(c) public sector debt at the start of year t equals public sector debt at the end of year t-1;
and

(d) the deviation in the real wage rate away from its forecast path in year t caused by a policy shock equals the deviation in year t-1 plus a term reflecting the gap in year t between the employment deviation and the deviation in labour supply.

3.1. Capital

In Mini-USAGE, investment in year t for industry i is a function of the expected rate of return in industry i. This is determined as a function of the rental and asset prices of i's capital in year t. Capital stock in industry i at the end of year t [$K1_i(t)$] equals capital stock at the start of year t depreciated [$K0_i(t)*(1-D_i)$] plus investment during year t [$I_i(t)$]:

$$K1_i(t) = K0_i(t) * (1 - D_i) + I_i(t) . \quad (3.1)$$

Without loss of generality we can assume that capital units are chosen so that the price of a unit of capital in year zero is one. This means that quantities of investment and start-of-year capital stocks for year zero can be read as data items from Tables 2.1 and 2.4. As can be discovered from the parameter files for Mini-USAGE, the depreciation rate for all industries is set at 0.07. Quantities of end-of-year capital stocks are calculated in the GEMPACK code according to (3.1). For example, the quantity of end-of-year capital stock for industry 1 in year 0 (1998) is

$$\begin{aligned} K1_1(1998) &= K0_1(1998) * (1 - 0.07) + I_1(1998) \\ &= 2495648*(1-0.07) + 265552 = 2586505 \end{aligned} \quad (3.2)$$

How do we ensure that the start-of-year capital stock in industry 1 in year 1 (1999) is 2586505?

Our initial solution for year 1 is the database for year 0. The start-of-year quantity of capital in industry 1 in our final solution should be 3.64 per cent higher than in our initial solution [$= 100*(2586505/2495648-1)$]. One possibility is to treat start-of-year capital stocks as exogenous variables in the year 1 computation. With this approach we would shock the start-of-year capital stock for industry 1 by 3.64 per cent. An alternative method, which we have found convenient, is to include in the GEMPACK code an equation of the form

$$d_K0_i(t) = [K1_B_i(t) - K0_B_i(t)]*del_unity \quad (3.3)$$

or equivalently,

$$K0_i(t)*ko_i(t) = 100*[K1_B_i(t) - K0_B_i(t)]*del_unity \quad (3.4)$$

where

$K0_B_i(t)$ and $K1_B_i(t)$ are the initial values for the start-of-year and end-of-year quantities of industry i's capital stock in the initial solution (or database) for year t;

$K0_i(t)$ is the start-of-year quantity of industry i 's capital stock in the current step in the computation of the final solution for year t ;
 $d_K0_i(t)$ is the change in the start-of-year quantity of industry i 's capital stock between the initial and final solutions for year t ;
 $ko_i(t)$ is the percentage change in the start-of-year quantity of industry i 's capital stock between the initial and final solutions for year t ; and
 del_unity is a variable that we move in the year t computation from an initial value of zero to a final value of 1.

3.2. Net foreign liabilities

We assume that net foreign liabilities at the end of year t [$NFL1(t)$] equals net foreign liabilities at the start of year t [$NFL0(t)$] plus the current account deficit for year t [$CADEF(t)$]:

$$NFL1(t) = NFL0(t) + CADEF(t) \quad . \quad (3.5)$$

To ensure that net foreign liabilities at the start of year t equals net foreign liabilities at the end of year $t-1$, we include in Mini-USAGE the equation:

$$d_NFL0(t) = [NFL1_B(t) - NFL0_B(t)] * del_unity \quad (3.6)$$

where

$NFL0_B(t)$ and $NFL1_B(t)$ are the initial values for the start-of-year and end-of-year net foreign liabilities in the initial solution (or database) for year t ;
 $d_NFL0(t)$ is the change in the start-of-year net foreign liabilities between the initial and final solutions for year t ; and
 del_unity is, as before, a variable that we move in the year t computation from an initial value of zero to a final value of 1.

As indicated in Table 2.3, we model the current account deficit for year t as imports minus exports plus servicing of foreign liabilities. In Mini-USAGE all foreign liabilities are assumed to be debt repayable in U.S. currency. In calculating servicing charges on the foreign debt we apply an interest rate to the start-of-year foreign debt.

3.3. Public sector debt

Public sector debt at the end of year t [$PSD1(t)$] equals public sector debt at the start of year t [$PSD0(t)$] plus the public sector deficit for year t [$GOVDEF(t)$]:

$$PSD1(t) = PSD0(t) + GOVDEF(t) \quad . \quad (3.7)$$

To ensure that public sector debt at the start of year t equals public sector debt at the end of year $t-1$, we include in Mini-USAGE the equation:

$$d_PSD0(t) = [PSD1_B(t) - PSD0_B(t)] * del_unity \quad (3.8)$$

where

$PSD0_B(t)$ and $PSD1_B(t)$ are the initial values for the start-of-year and end-of-year public sector debt in the initial solution (or database) for year t ;

$d_PSD0(t)$ is the change in the start-of-year public sector debt between the initial and final solutions for year t ; and del_unity is, as before, a variable that we move in the year t computation from an initial value of zero to a final value of 1.

The components in our modelling of the public sector deficit can be seen in Table 2.2. In calculating net interest on public sector debt, we apply an interest rate to the start-of-year public sector debt.

3.4. Wage determination in policy runs

In many general equilibrium analyses of the effects of changes in policy instruments and other changes in the economic environment, one of the following two assumptions is made:

- a. real wages adjust so there is no effect on employment; or
- b. real wages remain unaffected and employment adjusts.

In MONASH-style models, we can take an intermediate position between a and b. We can assume that real wages are sticky in the short run and flexible in the long run. In this case, favourable shocks generate short-run gains in aggregate employment and long-run gains in real wages.

More specifically, in MONASH-style policy simulations, we usually assume that the deviation in the real wage rate from its basecase forecast level increases at a rate which is proportional to the deviation in aggregate hours of employment from its basecase forecast level. The coefficient of proportionality is chosen so that the employment effects of a shock to the economy are largely eliminated after 5 years. This labour market assumption is consistent with conventional macro-economic modelling in which the NAIRU is either exogenous or only weakly dependent on real wage rates.

The version of this theory that we include in Mini-USAGE can be written algebraically as:

$$\left\{ \frac{W^P(t)}{W^f(t)} - 1 \right\} = \left\{ \frac{W^P(t-1)}{W^f(t-1)} - 1 \right\} + \alpha \left\{ \frac{E^P(t)}{E^f(t)} - 1 \right\} \quad (3.9)$$

where

$W^P(\tau)$ and $W^f(\tau)$ are the real before-tax wage rate in the policy and forecast runs in year τ ;

$E^P(\tau)$ and $E^f(\tau)$ are aggregate employment in the policy and forecast runs in year τ ;

and

α is a positive parameter.

In implementing the Johansen/Euler solution method, we need a change form of (3.9). As in our earlier representations of dynamic processes, we make use of base period coefficients and the del_unity variable. In our code for Mini-USAGE we represent (3.9) as:

$$\frac{W^P(t)}{W^f(t)} [w^P(t) - w^f(t)] = 100 * \left[\frac{WB^P(t)}{WB^f(t)} - \frac{WLB^P(t)}{WLB^f(t)} \right] * \text{del_unity} + \alpha * \frac{E^P(t)}{E^f(t)} [e^P(t) - e^f(t)] \quad (3.10)$$

In this equation

$WB^P(t)$ is the initial solution for the real before-tax wage rate in year t in the policy run, that is the final solution for this variable in the policy run for year $t-1$.⁶

$WLB^P(t)$ is the initial solution for the lagged real before-tax wage rate in year t in the policy run. This is the final solution for the lagged real before-tax wage in year $t-1$, which is the final solution for the real before-tax wage rate in the policy run for year $t-2$.

$WB^f(t)$ and $WLB^f(t)$ are the corresponding coefficients for the forecast run.

$w^P(t)$ and $w^f(t)$ are the percentage changes in the real before-tax wage rate between the initial and final solutions for year t in the policy and forecast runs.

$e^P(t)$ and $e^f(t)$ are the percentage changes in aggregate employment between the initial and final solutions for year t in the policy and forecast runs.

4. Divisia indexes: Mini-USAGE in its development role

4.1. Divisia problems

MONASH-style models contain many Divisia indexes for macro quantities and prices. Divisia indexes or approximations to them are also favoured by statistical agencies. However, they lead to problems. First they can indicate differences in the effects of alternative policies on macro aggregates for a given year where no differences exist. Second they can indicate spurious policy-induced changes in long-run growth rates.

To illustrate the first problem, we start by considering a Divisia price index for consumption. The percentage movement (p_t) in such an index between years $t-1$ and t is defined by

$$p_t = \sum_i S_{it} p_{it} \quad , \quad (4.1)$$

where

p_{it} is the percentage movement in the price of good i between years $t-1$ and t , and

⁶ For year zero, “the final solution” is the initial database.

S_{it} is the budget (or value) share of good i , averaged across years $t-1$ and t .⁷

The problem with Divisia price indexes (or other variable weight price indexes) is that their movement between years 0 and τ cannot be determined simply from information on prices and value shares in years 0 and τ . This is illustrated in Table 4.1 which shows basecase forecasts and two policy simulations. In the forecast simulation there are no movements in prices and value shares through the simulation period. In the policy simulations the prices of both commodities increase from 1 to 2. The time paths of these price increases are the same in the two policy simulation (although this is not an essential aspect of this example). In the first policy simulation there is a policy-induced taste change in year 2 favouring good 2 and leading to a change in budget shares. In the second policy simulation there is a similar policy-induced taste change but it takes place in year 1 rather than year 2. Although the two policy simulations have the same values for prices and budget shares in year 2, the Divisia price index in year 2 is 1.8750 in the first policy simulation and 2.1875 in the second. We are in danger of concluding that the first policy causes an 87.5 per cent increase in the price level after two years and that the second causes a 118.75 per cent increase. However, it is clear that both policies cause a 100 per cent increase.

To illustrate how a Divisia index can indicate spurious long-run growth effects, we consider a quantity index for capital. In the Divisia formulation, the percentage movement in aggregate capital from year $t-1$ to year t in simulation j is given by

$$k^j(t) = \sum_i S_i^j(t) * k_i^j(t) \quad (4.2)$$

where

$k_i^j(t)$ is the rate of growth from year $t-1$ to year t in industry i 's capital stock in simulation j either the forecast simulation ($j = f$) or the policy simulation ($j = p$); and

$S_i^j(t)$ is the share in simulation j of industry i in the aggregate capital stock for year t .

Equation (4.2) implies that the difference between the growth rates in year t of aggregate capital stock in policy and forecast simulations is given by:

$$k^p(t) - k^f(t) = \sum_i [S_i^p(t) - S_i^f(t)] * k_i^{ave}(t) + \sum_i [k_i^p(t) - k_i^f(t)] * S_i^{ave}(t) , \quad (4.3)$$

where the superscript *ave* denotes the average of values in the policy and forecast simulations.

⁷ In an N step Johansen/Euler computation, we can think of the average budget share for good i across years $t-1$ and t as being an N th of the sum of the i -budget shares at the N steps.

Table 4.1. Paths of Divisia Indexes in Dynamic Simulations

	Year 0	Year 1	Year 2
<i>Forecast</i>			
P1, level	1	1	1
P2, level	1	1	1
S1, share		0.5	0.5
S2, share		0.5	0.5
p1, % change		0	0
p2, % change		0	0
p, % change in index		0	0
P, level of index	1	1	1
<i>Policy case 1 (taste change in year 2)</i>			
P1, level	1	1	2
P2, level	1	2	2
S1, share		0.5	0.25
S2, share		0.5	0.75
p1, % change		0	100
p2, % change		100	0
p, % change in index		50	25
P, level of index	1	1.5	1.8750
<i>Policy case 2 (taste change in year 1)</i>			
P1, level	1	1	2
P2, level	1	2	2
S1, share		0.25	0.25
S2, share		0.75	0.75
p1, % change		0	100
p2, % change		100	0
p, % change in index		75	25
P, level of index	1	1.75	2.1875

We refer to the first term on the RHS of (4.3) as a share effect. Via the share effect, the growth rate of aggregate capital in year t in the policy simulation can fall short of that in the forecast simulation [$k^P(t) - k^f(t) < 0$] if the policy reduces the capital shares [$S_i^P(t) - S_i^f(t) < 0$] of industries with fast rates of capital growth [high $k_i^{ave}(t)$]. We refer to the second term on the RHS of (4.3) as a quantity effect. The quantity effect will be negative if the policy reduces capital growth rates [$k_i^P(t) - k_i^f(t) < 0$].

In an application of a MONASH-style model in which the policy shock is unfavourable to industry i , we will find in early years of the simulation period that $k_i^P(t) - k_i^f(t) < 0$. Eventually the gaps between the policy and forecast growth rates close [$k_i^P(t) - k_i^f(t)$ becomes approximately zero for all i]. Thus, the quantity effect makes no further contribution to the gap between $k^P(t)$ and $k^f(t)$. However the share effect can remain

nonzero indefinitely. For example, if the policy reduces the long-run share of industry i in the value of capital [$S_i^p(t) - S_i^f(t) < 0$ for all $t > 5$, say] and industry i 's capital is relatively fast-growing in the forecast run [$k_i^{ave}(t)$ is large], then the policy can permanently reduce the growth rate of the Divisia measure of aggregate capital [$k^p(t) - k^f(t) < 0$ for all $t > 5$, say]. Thus we are in danger of concluding that the policy causes a permanent change in the long-run growth rate of the economy's capital stock, even though it has no effect on long-run capital growth in any industry.

4.2. Providing alternative indexes that avoid the Divisia problem

If we want to look at the effects of a policy in year t , then we should compare the state of the economy in year t with the policy in place with its state without the policy. The fundamental problem in using year- t , policy-induced deviations in Divisia indexes is that their values depend on the path by which the economy arrived at year t . They do not depend just on the situation *in* year t .

As a step towards providing full-scale MONASH-style models with legitimate indicators of policy-induced changes in macro variables, we have added code (see Appendix) to Mini-USAGE for calculating Laspeyres and Paasche indexes. Values of these indexes for year t depend only on prices and quantities in year t .

We define policy-induced deviations for year t in Laspeyres quantity and prices indexes [$Lq(t)$ and $Lp(t)$] as forecast-share-weighted averages of percentage deviations in component quantities and prices:

$$Lq(t) = 100 * \frac{\sum_i P_i^f(t) * X_i^p(t) - \sum_i P_i^f(t) * X_i^f(t)}{\sum_i P_i^f(t) * X_i^f(t)} \quad (4.4)$$

$$= 100 * \frac{\sum_i P_i^f(t) * X_i^f(t)}{\sum_j P_j^f(t) * X_j^f(t)} * \left[\frac{X_i^p(t) - X_i^f(t)}{X_i^f(t)} \right] \quad (4.5)$$

and

$$Lp(t) = 100 * \frac{\sum_i P_i^p(t) * X_i^f(t) - \sum_i P_i^f(t) * X_i^f(t)}{\sum_i P_i^f(t) * X_i^f(t)} \quad (4.6)$$

$$= 100 * \frac{\sum_i P_i^f(t) * X_i^f(t)}{\sum_j P_j^f(t) * X_j^f(t)} * \left[\frac{P_i^p(t) - P_i^f(t)}{P_i^f(t)} \right]. \quad (4.7)$$

where $P_i^f(t)$, $P_i^p(t)$, $X_i^f(t)$ and $X_i^p(t)$ are the prices and quantities of i in year t in the forecast and policy runs.

To define policy-induced deviations for year t in Paasche quantity and prices indexes we recall that a macro value can be expressed as the product of a Laspeyres quantity index and a Paasche price index and as the product of a Paasche quantity index and a Laspeyres price index. Thus we can compute the policy-induced deviations for year t in Paasche quantity and prices indexes [$Pq(t)$ and $Pp(t)$] via:

$$1 + \frac{V^p(t) - V^f(t)}{V^f(t)} = \left[1 + \frac{Lq(t)}{100} \right] * \left[1 + \frac{Pp(t)}{100} \right] = \left[1 + \frac{Pq(t)}{100} \right] * \left[1 + \frac{Lp(t)}{100} \right] \quad (4.8)$$

where $V^f(t)$ and $V^p(t)$ are macro values in year t in the forecast and policy runs.⁸

As can be seen from the Appendix, the code for the Laspeyres and Paasche indexes is quite cumbersome. For testing and refining it, Mini-USAGE provided a valuable service by allowing quick turnaround. In the rest of this section we briefly look at some Mini-USAGE results generated during the testing procedure.

For our test experiment, we conducted forecast and policy runs for 1999 to 2007. In the forecast run we used actual data for most exogenous variables for the years up to 2004. Beyond 2004, the forecasts for the exogenous variables were based mainly on trends. In the policy run, the shock was a 5 per cent reduction in the power of the tariff on the high-protection good (a reduction in the tariff rate from about 10 per cent to about 5 per cent) imposed in 1999.

Chart 4.1 shows percentage deviations generated in the test experiment for Divisia, Laspeyres and Paasche indexes of real GDP. The Divisia results emerge naturally in MONASH-style models solved by the Johansen/Euler method. They are obtained as percentage differences between the policy and forecast levels of Divisia real GDP indexes. These are calculated by accumulating year-to-year real GDP growth. In run j (j = policy or forecast), growth from year $t-1$ to year t in real GDP is obtained from:

$$gdpr^j(t) = S_c^j(t) * cr^j(t) + S_i^j(t) * ir^j(t) + S_g^j(t) * gr^j(t) + S_x^j(t) * xr^j(t) - S_m^j(t) * mr^j(t) \quad (4.9)$$

⁸ Paasche quantity and price deviations are defined by

$$Pq(t) = 100 * \frac{\sum_i P_i^p(t) * X_i^f(t)}{\sum_j P_j^f(t) * X_j^f(t)} * \left[\frac{X_i^p(t) - X_i^f(t)}{X_i^f(t)} \right] \quad \text{and} \quad Pp(t) = 100 * \frac{\sum_i P_i^f(t) * X_i^p(t)}{\sum_j P_j^f(t) * X_j^p(t)} * \left[\frac{P_i^p(t) - P_i^f(t)}{P_i^f(t)} \right].$$

where $cr^j(t)$, $ir^j(t)$, $gr^j(t)$, $xr^j(t)$, and $mr^j(t)$ are rates of growth in run j from year $t-1$ to year t in Divisia quantity indexes for private consumption, investment, government consumption, exports and imports; and

$S_c^j(t)$, $S_i^j(t)$, $S_g^j(t)$, $S_x^j(t)$ and $S_m^j(t)$ are GDP shares in year t of run j .

The Laspeyres and Paasche results for real GDP deviations are calculated in the new code being tested in Mini-USAGE. For the Laspeyres deviations, we use a Laspeyres combination of deviations in components of real GDP, with the deviations in the components themselves being Laspeyres deviations. Similarly, for the Paasche deviations we use a Paasche combination of deviations in components of real GDP, with the deviations in the components being Paasche deviations.

Charts 4.2 to 4.4 show deviation results for aggregate employment and aggregate capital calculated as percentage deviations in Divisia, Laspeyres and Paasche indexes of industry employment and capital. As can be seen in these charts, the tariff cut generates a short-run increase in employment and a sustained increase in capital. The explanation of these results is not relevant for our present purposes. Here we focus on the deviations in the alternative indexes of real GDP.

A good starting point for thinking about policy-induced deviations in real GDP is the aggregate production function:

$$Y = A * F(K, L) \quad (4.10)$$

where Y is real GDP, K and L are inputs of capital and labour, and A is a total-factor-productivity term. In our tariff-cut simulation, we assumed no policy-induced changes in technology (the technology variables follow the same paths in the forecast and policy runs). Nevertheless, the tariff cut can still affect A . This is because A reflects not only technology but also captures the effects on GDP of changes in the efficiency with which capital and labour are allocated between industries and expenditure is allocated between goods. On the basis of the usual consumer-surplus diagram, we would expect the total-factor productivity or efficiency effect in our tariff-cut experiment to be approximated by:

$$\text{eff}(t) = \left(\frac{T_2^p(t) + T_2^f(t)}{200} \right) * SM_2(t) * m_2(t) \quad (4.11)$$

where

$\text{eff}(t)$ is the percentage increase in real GDP in year t generated by the policy-induced reduction in the deadweight loss associated with the tariff on the high protection good (good 2);

Chart 4.1. Policy-induced percentage deviations in real GDP calculated with different indexes

Chart 4.2. Policy-induced percentage deviations in real GDP, employment and capital: Divisia indexes

**Chart 4.3. Policy-induced percentage deviations in real GDP, employment and capital:
Laspeyres indexes**

**Chart 4.4. Policy-induced percentage deviations in real GDP, employment and capital:
Paasche indexes**

$T_2^p(t)$ and $T_2^f(t)$ are the tariff rates applying to good 2 in year t of the policy and forecast runs;

$SM_2(t)$ is the c.i.f. value of imports of good 2 in year t expressed as a share of GDP; and

$m_2(t)$ is the policy-induced percentage deviation in the quantity of imported good 2.

In all simulation years, $T_2^p(t)$ is 5 per cent and $T_2^f(t)$ is 10 per cent. From the Mini-USAGE database, we find that $SM_2(t)$ is about 0.0123 [= 104012/8443540]. From our simulation results we find that $m_2(t)$ is about 3.7 per cent for all t . Bringing all these numbers together in (4.11), gives

$$\text{eff}(t) = \left(\frac{5+10}{200} \right) * 0.0123 * 3.7 = 0.0034 \quad . \quad (4.12)$$

Thus we would expect our results to show a policy-induced total-factor-productivity increase (increase in A) for all years of about 0.0034 per cent.

With a long-run policy-induced increase in K , no long-run reduction in L and a policy-induced increase in A , real GDP as commonly understood should show a long-run policy-induced increase. This happens with both the Laspeyres and Paasche measures, but not with the Divisia measure.

Quantitatively, we would expect the long-run policy-induced percentage increase in real GDP to be approximated by

$$\text{gdpr_dev} = S_k * k_dev + S_\ell * \ell_dev + a_dev \quad (4.13)$$

where

gdpr_dev , k_dev and ℓ_dev are long-run policy-induced percentage deviations in real GDP and the quantities of capital and labour;

S_k and S_ℓ are capital and labour shares in GDP; and

a_dev is the long-run policy-induced percentage deviation in factor productivity.

In our database, S_k and S_ℓ are approximately 0.275 and 0.725. Substituting these numbers into (4.13) and using the long-run capital and labour deviations shown in Charts 4.2 to 4.4 together with the efficiency calculation from (4.12), we can obtain back-of-the-envelope estimates of deviations in real GDP. As can be seen from Table 4.2, the Laspeyres and Paasche calculations accord with our expectations but the Divisia measure of the real GDP deviation is very much at odds with what would be expected on the basis of (4.13).

Table 4.2. Long-run real GDP deviations

	From (4.13)	Simulation result
Divisia	0.0064	-0.0010
Laspeyres	0.0069	0.0067
Paasche	0.0061	0.0046

What is it that causes the Divisia measure to go wrong? We traced the problem to the share effect [see the discussion of (4.3)] associated with aggregate imports. The contribution of this share effect to the difference between the real GDP growth rates [$gdpr^p(t) - gdpr^f(t)$] in year t in the policy and forecast runs is:

$$\text{Share effect, imports} = -[S_m^p(t) - S_m^f(t)] * \left[\frac{mr^p(t) + mr^f(t)}{2} \right] \quad (4.14)$$

The cut in protection permanently raises the share of imports in GDP, that is

$$S_m^p(t) > S_m^f(t) \quad \text{for all } t, \quad (4.15)$$

and in our forecasts, real imports are a fast growing component of real GDP. We found that this was sufficient to cause the tariff cut in 1999 to have a permanent long-run negative effect on the rate of growth of the Divisia index of real GDP. Thus when we compare Divisia indexes of real GDP in the policy and forecast runs, we find ever increasing negative policy-induced deviations.

5. Concluding remarks

An effective way to find out about an economic model is to run simulations and to look at results. Not many people have the time or inclination to do this with detailed MONASH-style models such as USAGE. The effort is just too large. However, running mini-USAGE and looking at results requires relatively little effort for people familiar with GEMPACK. Thus, by creating Mini-USAGE we hope to expose USAGE mechanisms and results to a wider audience. We also hope that Mini-USAGE will be a useful starting point for other modelling efforts.

In our own research, we are finding that Mini-USAGE is useful vehicle for testing new developments. As described in Section 4, we have found that the Divisia indexes used in MONASH-style models can sometimes produce misleading results. We are planning to provide alternative indexes in full-scale MONASH-style models. Mini-USAGE has been valuable in developing and testing these alternatives.

The documentation provided here for Mini-USAGE is brief. We are catering for people who like to try things out and to look at instructions for occasional guidance. We hope that users of Mini-USAGE who would like more depth on particular aspects of MONASH-style models will refer some of the detailed documentation cited in our first footnote.

! Subsection 8.18: Equation for converting twists into tech/taste changes !

! In forecasting it is convenient to use twist variables to accommodate information on imports and on primary factor inputs. The twists on imports, for example, allow exogenously specified growth in aggregate imports to be accommodated by a cost neutral change in the import/domestic quantity share in all uses of imports. The cost neutral changes are equivalent to domestic- and import-saving technical and taste changes. These are calculated in the equations below when the shift variables are set exogenously on zero. In policy we usually endogenize the shift variables and exogenize the technical and taste changes. This ensures that the technical and taste changes in policy are the same as those in forecast. If instead we exogenize the twists in policy, then we impart different tech changes in policy than in forecast. This is because import/domestic shares are different in policy than in forecast. With different tech changes in policy than in forecast, interpretation of the policy results becomes difficult. !

Equation E_alcsi_dom # Converts twist into tech change, intermed. domestic #

(All,c,COM)(All,i,IND)
alcsi(c,"dom",i) = [S1(c,"imp",i)/(SIGMA1(c)-1)]*twist_src(c)
+ f_alcsi(c,"dom",i);

Equation E_alcsi_imp # Converts twist into tech change, intermed. imported #

(All,c,COM)(All,i,IND)
