DRAFT – April 2008

ABSTRACT

Human-generated greenhouse gases depend on the level of economic activity. Therefore, most climate change studies are based on models and scenarios of economic growth. Economic growth itself, however, is likely to be affected by climate change impacts. These impacts affect the economy in multiple and complex ways: changes in productivity, resource endowments, production and consumption patterns. Moreover, impacts affect expected capital returns, international capital flows, savings and investments.

We use a dynamic, multi-regional CGE model of the world economy to explore all these issues. We compare economic growth paths for the various regional economies, to answer the following questions: Will climate change impacts significantly affect growth and wealth distribution in the world? Should forecasts of human induced greenhouse gases emissions be revised, once climate change impacts are taken into account?

KEYWORDS: Computable General Equilibrium Models, Climate Change, Economic Growth.

JEL CODES: C68, E27, O12, Q54, Q56

1. Introduction

Climate change is affected by the concentration of greenhouse gases (GHG) in the atmosphere, which depends on human and natural emissions. In particular, the human, or anthropogenic, contribution to this phenomenon is widely recognized as the main driver of climate change (IPCC, 2007).

*Corresponding author. Address: Dipartimento di Scienze Economiche, Cannaregio 873, 30121, Venezia, Italy. E-mail: roson@unive.it.
Therefore, in order to estimate future climate, climatologists need to understand how much GHGs emissions will be generated, and this information is provided by models and scenarios of socio-economic growth. The Intergovernmental Panel on Climate Change (IPCC), for instance, provides a number of alternative socio-economic scenarios (so-called “SRES” scenarios), which are typically used to create input data for GCM models, forecasting future climate (Nakicenovic and Swart, 2000).

Very little is known, however, about the reverse causation, by which climate change would affect economic growth, both quantitatively and qualitatively. Understanding how climate change will influence the global economy is obviously very important. This allows assessing the intrinsic auto-adjustment system capability, identifying income and wealth distribution effects and verifying the robustness of socio-economic scenarios.

Unfortunately, the issue is very complex, because there are many diverse economic impacts of climate change, operating at various levels. Some previous studies (Berritella et al., 2006; Bosello et al., 2006; Bosello et al., 2007; Bosello and Zhang, 2006) have used Computable General Equilibrium Models to assess sectoral impacts, using a comparative static approach. This paper builds upon these studies, but innovates by considering many climate change impacts simultaneously and, most importantly, by considering dynamic impacts in a specially designed dynamic CGE model of the world economy (ICES).

Using a dynamic model allows us to investigate the increasing influence of climate change on the global economic growth. This influence is twofold: on one hand, the magnitude of physical and economic impacts will rise over time and, on the other hand, endogenous growth dynamics is affected by changes in income levels, savings, actual and expected returns on capital.

We typically find that climate change is associated with significant distributional effects, for a number of reasons. First, not all impacts of climate change are negative. For example, milder climate attracts tourists in some regions, reduced need for warming in winter times saves energy, incidence of cold-related diseases is diminished, etc. Second, changes in relative competitiveness and terms of trade may allow some regions and industries to benefit, even from a globally negative shock. Third, higher (relative) returns on capital, possibly due to changes in demand structure and resource endowments, could foster investments and growth. All these effects can hardly be captured by a stylized macroeconomic model, and require instead a disaggregated model with explicit representation of trade links between industries and regions.

The paper is organised as follows. Section 2 presents the ICES model structure and explains how a baseline scenario is built. Climate change impacts are analysed in Section 3. Section 4 illustrates the
simulation results, assessing how climate change impacts will affect regional economic growth in the world. The last section draws some conclusions.

2. The ICES Model

ICES (Inter-temporal Computable Equilibrium System) is a dynamic, multi-regional CGE model of the world economy, derived from a static CGE model named GTAP-EF (Roson, 2003; Bigano et al., 2006).\(^1\) The latter is a modified version of the GTAP-E model (Burniaux and Troung, 2002), which in turn is an extension of the basic GTAP model (Hertel, 1997).

ICES is a recursive model, generating a sequence of static equilibria under myopic expectations, linked by capital and international debt accumulation. Although its regional and industrial disaggregation may vary, the results presented here refer to 8 macro-regions and 17 industries, listed in Table 1.

Growth is driven by changes in primary resources (capital, labour, land and natural resources), from 2001 (calibration year of GTAP6 database) onward. Dynamics is endogenous for capital and exogenous for others primary factors.

Population forecasts are taken from the World Bank\(^2\), while labour stocks are changed year by year, according to the International Labour Organization (ILO) annual growth rates estimates\(^3\). Estimates

---

1. Detailed information on the model can be found at the ICES web site: [http://www.feem-web.it/ices](http://www.feem-web.it/ices).

3. Available at [http://laborsta.ilo.org](http://laborsta.ilo.org). The annual percentage growth rate in the period 2001-2020 has been applied to the longer period 2001-2050.
of labour productivity (by region and industry) are obtained from the G-Cubed model (McKibbin and Wilcoxen, 1998). Land productivity is estimated from the IMAGE model (IMAGE, 2001). Since natural resources are treated in GTAP in a rather peculiar way (Hertel and Tsiga, 2002, Dimaranan, 2006), these factor stocks are endogenously estimated in the ICES model, by fixing their price. For fossil fuels (oil, coal and gas), we use EIA forecasts (EIA, 2007), whereas for other industries (forestry, fishing) the resource price is changed in line with the GDP deflator. Regional investments and capital stocks are determined as follows. Savings are a constant fraction of regional income. All savings are pooled by a virtual world bank, and allocated to regional investments, on the basis of the following relationship:

\[
\frac{I_r}{Y_r} = \phi_r \exp(\rho_r (r_r - r_w))
\]

where: \(I_r\) is regional annual investment, \(Y_r\) is regional income, \(r_r\) is regional and world returns on capital, \(\phi_r, \rho_r\) are given parameters.

The rationale of (1), which has been adopted from the ABARE GTEM model (Pant, 2002), is quite simple. Whenever returns on capital (that is, the price of capital services) do not differ from those in the rest of the world, investments are proportional to regional income, like savings are. In this case, current returns are considered as proxies of future returns. If returns are higher, or lower than the world average, then investments are higher or lower too. The \(\rho_r\) parameter determines the sensitivity of investment supply to returns differentials.

Investments affect the evolution of capital stock, on the basis of a standard relationship with constant depreciation:

\[
K_r^{t+1} = I_r^t + (1 - \delta) K_r^t
\]

Of course, relationships like (1) do not ensure the equalization of regional investments and savings, and any region can be creditor or debtor vis-à-vis the rest of the world. Because of accounting identities, any excess of savings over investments always equals the regional trade balance \(TB_r\), so there is a dynamics of the debt stock, similar to (2), but without depreciation:

\[
D_r^{t+1} = TB_r^t + D_r^t
\]

Foreign debt is initially zero for all regions, then it evolves according to (3). Foreign debt service is paid in every period on the basis of the world interest rate \(r_w\).

\[\text{\textsuperscript{4}}\text{Therefore, the upper level of the utility function for the representative consumer is Cobb-Douglas. Intertemporal utility maximization is implicit.}\]

\[\text{\textsuperscript{5}}\text{This is set in the model by equating global savings and investments.}\]
Consider now how an external shock, like those associated with climate change impacts, affects economic growth.

If the shock is a negative one, a decrease in regional GDP proportionally lowers both savings and investments. Any difference between these two variables, which amounts to a change in foreign debt stock and trade balance, must then be associated with changing relative returns on capital, according to (1). Most (but not all) negative effects of climate change (losses of capital, land, natural resources, or lower labour productivity) imply an higher relative scarcity of capital, thereby increasing returns. In this case, the shock is partially absorbed by running a foreign debt, which must eventually be repaid.

If the negative shock would last one or few periods, this mechanism amounts to spreading the negative shock over a longer interval, allowing a smoother adjustment in the regional economy. However, climate change impacts typically increase over time, so the foreign debt or credit tends to constantly rise, introducing some kind of delay in the response to shocks in the regional economies. Since the shocks we are applying in the model rise in magnitude over time, if an economy starts attracting foreign investments, it will continue to do so over all the subsequent years, and vice versa. Therefore, the capital accumulation process tends to make this economy growing at higher rates, in comparison with the baseline, in which climate change impacts are absent. A comparison of growth paths for this economy, with and without climate change, would then highlight (non-linearly) divergent paths.

This dynamic effect overlaps with the direct impacts of climate change. The direct impacts would make each regional economy growing faster or lower, in a linear fashion. The difference between the two scenarios is shaped by this overlapping. If direct and indirect effects work to the same direction, macroeconomic variables (like GDP) will progressively diverge (positively or negatively). On the other hand, if the two effects are opposite, the direct effect would prevail at first, then the capital accumulation will eventually drive the economic growth, possibly inverting the sign of the total effects.

3. Modelling Climate Change Impacts

Earlier studies (Berritella et al., 2006; Bosello et al., 2006; Bosello et al., 2007; Bosello and Zhang, 2006) have used CGE models to assess the economic implications of climate change impacts. Simulations are performed by identifying the relevant economic variables, and imposing changes in some model parameters, like:
• Variations in endowments of primary resources. For example, effects of sea level rise can be simulated by reducing stocks of land and capital (infrastructure).

• Variations in productivity. Effects of climate change on human health can be simulated through changes in labour productivity. Effects on agriculture can be simulated through changes in crop productivity.

• Variation in the structure of demand. Although demand is typically endogenous in a general equilibrium model, shifting factors can mimic changes in demand not induced by variations in income or prices. In this way, it is possible to simulate: changing energy demand for heating and cooling, changing expenditure on medical services, changing demand for services generated by tourists, etc.

Comparative static CGE models can usefully highlight the structural adjustments triggered by climate change impacts, by contrasting a baseline equilibrium at some reference year with a counterfactual one, obtained by shocking a set of parameters. In a dynamic model like ICES, parameters are varied in a similar way, but in each period of the sequence of temporary equilibria.

We run the model at yearly time steps from 2001 to 2050. In each period, the model solve for a general equilibrium state, in which capital and debt stocks are “inherited” from the previous period, and exogenous dynamics is introduced through changes in primary resources and population. In addition, impacts are simulated by “spreading” the climate change effects over the whole interval 2001-2050. For example, changes in crop productivity are related to changes in temperatures and precipitation. As temperatures progressively rise over time, wider variations are imposed to the model productivity parameters.

In this way, the model generate two sets of results: a baseline growth path for the world economy, in which climate change impacts are ignored, and a counterfactual scenario, in which climate change impacts are simulated. The latter scenario differs from the basic one, not only because of the climate shocks, but also because exogenous and endogenous dynamics interact, and climate change ultimately affect capital and foreign debt accumulation.

We consider here five climate change impacts, related to: agriculture, energy demand, human health, tourism and sea level rise. In all cases, we adapt for the dynamic model some input data previously used in static CGE models.

Agricultural impact estimates are based on Tol (2002) who extrapolated changes in specific yields for some scenarios of climate change and temperature increase.
To evaluate how energy demand reacts to changing temperatures, we use demand elasticities from De Cian et al. (2007). This study investigates the effect of climate change on households’ demand for different energy commodities.

Two impacts related to human health are considered: variation in working hours, reflecting changes in mortality and morbidity, and variation in the expenditure for health care services, undertaken by public administrations and private households (Bosello et al., 2006).

Coastal land loss due to sea level rise was estimated by elaborating results from the Global Vulnerability Assessment (Hoozemans et al., 1993), integrated with data from Bijlsma et al. (1996), Nicholls and Leatherman (1995), Nicholls et al. (1995) and Beniston et al. (1998). The methodology and some results are illustrated in Bosello et al. (2006).

Finally, climate change impacts on tourism are obtained from the Hamburg Tourism Model (HTM) (Bigano et al., 2005), which is an econometric model, estimating tourism flows on the basis of average temperature, coastal length, population, prices and income.

Table 2 summarizes the exogenous shocks introduced in the model to simulate the climate change impacts.

4. Simulation Results

We present here the simulation results by focusing on the differences between the baseline and the climate change impact scenarios. Our aim is twofold: assessing the economic consequences of climate change on growth and income distribution in the world, and verifying whether considering the climate change feedback on economic scenarios brings about significant variations in estimates of emissions of greenhouse gases.

Let us first consider each of the five impacts separately, by looking at the differences generated between the two scenarios in the regional GDP. Figure 1 presents differences in GDP in the period 2001-2050, obtained by simulating a progressive change in land productivity, as reported in Table 2. Land productivity is generally reduced. This hits more severely some agriculture-based, relatively poorer economies, but some other regions get benefits, primarily because of positive changes in the terms of trade.

Figure 1 – Agriculture impacts – Differences in regional GDP

Figure 2 shows a similar picture, referred to climate change impacts on energy demand. Here we have a more differentiated picture: some regions lose, some other gains, whereas the world average is about the same. This should be expected, because of the nature of the shock, which modifies the structure of demand without affecting the endowments of primary resources. Furthermore, from Table 2 we see that demand for coal and oil products is generally reduced,
whereas demand for electricity increases significantly in China, India and Energy Exporting Countries.

Figure 2 – Energy demand impacts – Differences in regional GDP

Focusing on real GDP, however, may suggest erroneous conclusions. Consider, for example, the case of Energy Exporting Countries (EEx). This region suffers from an adverse shock in the terms of trade. This means that more exports are needed to pay for imports: real GDP increases, but nominal GDP and welfare decrease.

Figure 3 – Human health impacts – Differences in regional GDP
Figure 3 illustrates the dynamic effect of climate change impacts on labour productivity and health services expenditure.

Two regions, which are the poorest in the world, experience losses, whereas the remaining regions get small benefits. The magnitude of the GDP variations is small, but we are considering here only monetary costs/gains of health impacts, disregarding the possible existence of catastrophic events. Notice the shape of the curves. This suggests that direct impacts of climate change and the indirect impacts of capital accumulation are opposite.

Figure 4 illustrates tourism impacts. Although the shape of the curves is different from the one in Figure 3, the regional distribution of gains and losses is quite similar. This suggests that most factors making a region unhealthy also make the same region less attractive as a tourist destination. However, the absolute value of impacts on the GDP is here much larger, particularly in poor regions, where tourism is a sizeable industry.

Figure 5 shows the sea level rise impact, generating losses of agricultural land, in the absence of any protective investment.
Variations are quite limited, as land losses are quite small in the aggregate. Again, poorer regions are the ones which experience the more significant reductions in GDP.

Figure 6 presents percentage variations in GDP generated by the joint action of all the impacts together. Notice that the total effect is not just the sum of all individual effects, as the various impacts interact and affect the endogenous growth mechanism.
We can see that the overall impact is fairly large, and the distributional consequences are significant, making the poorest countries worse off. In other words, climate change works against equity and income convergence in the world.

The next two figures show the industrial effects. Figure 7 presents the percentage deviations in the physical output of the various industries, whereas Figure 8 presents the corresponding variations in prices.

**Figure 7 – Differences in industrial output**

**Figure 8 – Differences in industrial prices**
In quantity terms, Electricity is the largest growing industry, whereas wheat production first increases, then declines. Significant reductions are observed in the Fishing, Gas, Rice and Other Industries.

Prices increases in most agricultural industries, particularly in Rice and Cereals, whereas prices are lower in the energy sector, most notably for Oil, Oil Products and Gas. An interesting question is whether emissions of greenhouse gases are affected by the changing growth of the world economy. ICES produces estimates of carbon dioxide (CO2), nitrous oxide (N2O) and methane (CH4). Figures 9, 10, 11 illustrate the percentage changes for these three gases between the two scenarios.

**Figure 9 – Differences in CO2 emissions**

We can see that emissions increase in some countries, and decrease in some other countries. There are quite small global variations, and this is good news for climatologists, adopting some given socio-economic scenarios for their analyses. They do not need to revise their assumptions about anthropogenic emissions.

More precisely, considering the different size and baseline volume of emissions, total emissions of greenhouse gases turn out to be slightly smaller, once the climate change feedback on the economy is taken into account.
Figure 10 – Differences in N2O emissions

Figure 11 – Differences in CH4 emissions
5. Conclusions
Climate change affects the world economy in many different ways. Using a dynamic general equilibrium model, we have been able to analyze the second-order, system-wide effects of climate change impacts and their consequences on growth.
We found that macroeconomic effects are sizeable but, most importantly, there are significant distributional effects at the regional and at the industrial level. In particular, we found that climate change works against equity and income convergence in the world.
On the other hand, global emissions of greenhouse gases are only a little diminished when the climate change feedback is considered. Therefore, constancy of human-generated emissions appears to be a reasonable approximation for most physical climate models.
