Abstract

This paper constructs a multi-sector dynamic general equilibrium model for a trading economy. We incorporate three major factors of production: capital, skilled labor & unskilled labor. We solve and calibrate the model using data from Japan and Korea. We then consider changes to immigration policy in both countries. We are able to examine the effects on output, consumption, wages, and utility. We do this for both the new steady state and for the time-path leading to that steady state. In addition, we are able, if we so wish, to impose a series of unrelated macroeconomic shock to the model. This has the advantage of allowing us to calculate confidence bands around our policy impulse response functions.

We find that allowing skilled labor to immigrate leads to greater welfare gains in the steady state. We also show that there is a great deal of uncertainty surrounding the exact time path to a new steady state in the presence of the typical fluctuations associated with business cycles. We find a great deal of inertia in the transition to a new steady state.

1. Introduction and Literature Review

Immigration issues are among the most political sensitive economic issues confronted by policy makers. Whether or not to allow workers from low wage countries to migrate to high wage countries is a source of constant political debate in these high wage countries. Western Europeans struggle with the optimal number of workers to allow to immigrate from Eastern Europe, North Africa and the Middle East. Americans confront issues of immigration from Mexico and other parts of Latin America, as well as from China and other countries in Asia.

Due to their relative isolation, Japan and South Korea have not struggled with immigration as much as other developed countries. In both cases entry into the country is more difficult than simply crossing a border. Japan is an island nation. South Korea is located on a peninsula with a heavily fortified demarcation line that makes it a de facto island when it comes to immigration.

As incomes have risen in these countries, however, the lure of higher wages as compared with neighboring countries has made them more attractive places to work. Both countries have fairly strict immigration constraints. Though there is pressure for these constraints to be relaxed. Manufacturers find attractive the lower wages that immigration would induce. Domestic workers find this correspondingly unattractive.

In recent years, South Korea has begun to relax its immigration constraints more than Japan has. In part this is due to the greater ability of ethnic Koreans living relatively closely in China to assimilate into South Korean society. Japan has no corresponding pool of ethnic Japanese living in low wage countries¹. Generally speaking, Japan favors immigration by highly skilled workers², whereas South Korea allows more lower-skilled or unskilled workers.

In this paper we examine the effects of various changes to immigration policy in these two countries. We build and calibrate a multi-sector dynamic general equilibrium (DSGE) model of these two economies and consider changes in the supply of both unskilled and various types of skilled labor. We are interested in the effects these policy changes will induce on the wages of existing domestic workers and on the aggregate effects on output, consumption and other key measures of economic activity.

¹ There is a sizeable ethnic Japanese population in Brazil. This can be observed in figure 2.

² See Fuess (2003) for an excellent summary.

This paper is not the first to examine these issues in this way. Choi (2004) builds a static general equilibrium model of the South Korean economy, for example. His model is similar in spirit to ours, but has important differences in the modeling. He allows for imperfect competition in intermediate goods which are produced using capital and skilled labor specific to the particular intermediate good. Final goods are perfectly competitive and produced with capital and unskilled labor. Choi focuses on the welfare effects of easing immigration restrictions and is concerned primarily with behavior in the short run as a result of business cycle movements. He reports the effects of various business cycle shocks to the economy on welfare and wage inequality.

Goto (1998) also builds and calibrates a small open computable general equilibrium (CGE) model for Japan. He groups goods into three categories: exportables, importables, and nontraded. Rather than aggregating into a single final good, he allows each of these to enter the utility function separately. Since the model is not explicitly dynamic, he holds capital in each production sector constant. Labor, however, is homogenous and mobile across sectors. Goto examines the effects of several shocks having to do with changes in trade and international prices. His most interesting result, however, is that small amounts of labor immigration reduce welfare, while sufficiently large amounts may actually improve welfare.

In contrast, this paper is explicitly dynamic and uses the tools of DSGE modeling. We focus on the long-run transition to a new steady state equilibrium. Business cycle movements are important only because they add uncertainty and volatility to this transition. By incorporating these shocks, however, we are able to present not only impulse responses of key variables to immigration shocks, but also derive confidence bands about these responses.

Section 2 below presents the theoretic model. Section 3 shows how the model can be rendered stationary and suitable for finding a steady state. We also show how this steady state can be found. In section 4 we discuss calibration of the model to data from Japan and Korea. We also present and discuss the steady state of a baseline calibration. Section 5 discusses possible policy changes to immigration and introduces the stylized policy changes we will simulate. In each of these cases we consider immigration policies that bring the foreign population to levels similar to those found in Germany and the U.S. Our policies differ in the mix of skilled and unskilled workers that are allowed to immigrate. In section 6 we simulate these cases for simple one-time changes in policy for an economy with no other source of

macroeconomic shocks. We are able to derive smooth transition paths from the initial steady state to the new one associated with the higher number of workers. Section 7 repeats these simulations while simultaneously allowing for macroeconomic shocks to technology and consumer confidence. By performing a large number of simulations for each case we are able to derive confidence bands for the key variables considered. Section 7 concludes the paper.

2. A Dynamic General Equilibrium Model

We construct a small open economy multi-sector dynamic general equilibrium model. Our model allows for a single non-traded final good (Y) which is used for both consumption (C) & investment in capital goods. The final good is produced using five intermediate goods via an Armington aggregator. The intermediate goods (Y_i) can be traded internationally or may be non-traded depending on the nature of the good. They are produced using capital (K) & two types of labor. The two types of labor are skilled and unskilled (N). Each intermediate good uses a unique type of skilled labor (L_i) which is therefore a specific factor. Unskilled labor can be used to produce any of the intermediate goods. All types of labor are supplied in fixed endowments. Capital is non-traded and accumulates optimally over time. Productivity (z_A) is exogenous and has both a trend and stochastic component. There is also a consumer confidence shock (z_R) which we model explicitly below which alters the household's perceived optimal time path for consumption and savings. Households may not save or borrow internationally and trade balances every period.

Each period households maximize utility from consumption. They supply capital and various forms of labor inelastically and save by holding physical capital. The typical consumer's problem is illustrated by the Bellman equation in (2.1) which maximizes subject to the budget constraint in (2.2).

$$V(K; \Theta) = \text{Max}_{K'} U(C) + \beta E\{e^{z_R'} V(K'; \Theta')\} \quad (2.1)$$

$$C = \sum_i w_i \bar{L}_i + v \bar{N} + (1 + r - \delta)K - K' \quad (2.2)$$

In these equations, w_i is the wage rate for skilled labor of type i , v is the wage for unskilled labor, r is the real rental rate for domestic capital, s is the real return on foreign bond, q is the real exchange rate (domestic units per foreign unit), δ is the depreciation rate of capital, C

is real consumption, K is holdings of real domestic capital, and Θ is the exogenous information set (prices, shocks, etc.).

The first-order conditions from this maximization problem reduce to the Euler equation in (2.3).

$$U_C = \beta \mathbf{E}\{e^{z_R} U_C'(1+r'-\delta)\} \quad (2.3)$$

With the assumption of a constant elasticity of substitution utility function this becomes equation (2.4).

$$C^{-\sigma} = \beta \mathbf{E}\{e^{z_R} C'^{-\sigma} (1+r'-\delta)\} \quad (2.4)$$

Final goods producers maximize profits from purchasing all five intermediate goods and producing the final output good, as shown in equation (2.5). The production function is an Armington aggregator and yields constant expenditure shares for each intermediate good in final production.

$$\text{Max}_{\{Y_i, X_i\}} \Pi_F = \prod_i F_i^{a_i} - \sum_i p_i F_i; \sum_i a_i = 1 \quad (2.5)$$

Here, F_i is the quantity of intermediate good used and p_i is its real price.

The first-order conditions reduce to equations (2.6) and (2.7).

$$p_i F_i = a_i Y \quad (2.6)$$

$$Y \equiv \prod_i F_i^{a_i} \quad (2.7)$$

Intermediate goods producers maximize profits from hiring capital and labor and selling a particular intermediate good as in equation (2.8).

$$\text{Max}_{K_i, L_i} \Pi_i = p_i K_i^{b_i} (e^{gt+z_A} N_i)^{c_i} (e^{gt+z_A} L_i)^{1-b_i-c_i} - r_i K_i - w_i L_i - v_i N_i \quad (2.8)$$

Here, N_i is the unskilled labor demanded in sector i , L_i is the skilled labor demanded in sector i , and z_A is a technology shock. The first-order conditions reduce to equations (2.9) – (2.12).

$$r_i K_i = b_i p_i Y_i \quad (2.9)$$

$$v_i N_i = c_i p_i Y_i \quad (2.10)$$

$$w_i L_i = (1 - b_i - c_i) p_i Y_i \quad (2.11)$$

$$Y_i \equiv K_i^{b_i} (e^{g^t+z_A} N_i)^{c_i} (e^{g^t+z_A} L_i)^{1-b_i-c_i} \quad (2.12)$$

All markets must clear and this clearing imposes additional restrictions on the model. Labor is not traded internationally, but some intermediate goods are. We allow exports for all intermediate goods and impose any relevant trade restrictions later in our simulations.

Clearing of the final goods market gives (2.13).

$$Y + (1 - \delta)K = C + K' \quad (2.13)$$

Clearing in the factor markets gives equation (2.14) – (2.16).

$$K = \sum_i K_i \quad (2.14)$$

$$\bar{N} = \sum_i N_i \quad (2.15)$$

$$\bar{L}_i = L_i \quad (2.16)$$

International trade in intermediate goods gives equation (2.17).

$$Y_i = F_i + X_i \quad \forall i \quad (2.17)$$

Here, X_i is exports of good i .

Balanced trade gives (2.18).

$$\sum_{i \in \text{traded}} p_i X_i = 0 \quad (2.18)$$

By Walras Law one of the equations in (2.13) – (2.18) is redundant. We choose to omit (2.18).

Mobility of capital and unskilled labor across sectors implies these factor prices must be identical across industries as in equations (2.19) and (2.20).

$$r_i = r \quad \forall i \quad (2.19)$$

$$v_i = v \quad \forall i \quad (2.20)$$

Traded goods are linked to foreign prices by (2.21a). This equation omits any tariffs, but this omission is unimportant since we use this only to calibrate the model and establish international prices consistent with observed trade patterns. We interpret these prices as being net of tariffs.

$$p_k = qp_k^*; k \in \text{traded} \quad (2.21a)$$

If goods are not traded then we replace equation (2.21a) with (2.21b) for that industry.

$$x_j = 0; j \in \text{nontraded} \quad (2.21b)$$

Finally, equations (2.22) and (2.23) specify the laws of motion for the two exogenous shock processes.

$$z_A' = \rho_A z_A + e_A'; e_A' \sim iid(0, \sigma_A^2) \quad (2.22)$$

$$z_R' = \rho_R z_R + e_R'; e_R' \sim iid(0, \sigma_R^2) \quad (2.23)$$

3. Stationarizing and the Model's Steady State Solution

Equations (2.2), (2.4), (2.6), (2.7), (2.9) – (2.17) and (2.19) – (2.23) are a system of eighteen dynamic equations that define the system.

We can reduce the dimensionality of the system by using (2.17) to substitute for the values of the F_i 's. We also define allocations of capital and unskilled labor over each of the I industries as shares of the totals and denote these shares as $\{\phi_i^K, \phi_i^N\}$. These replace the variables K_i and N_i . Finally we define the export share in an intermediate industry as $x_i \equiv X_i/Y_i$ and replace the X_i 's.

As specified, the system generates data that are non-stationary and our solution technique requires linear approximations of these equations about a steady state. Therefore, it is necessary to redefine variables in a way that renders the model stationary.

Equation (2.12) shows that technology is growing with a trend growth rate of g . Hence we can transform all growing variables $(K, \{v_i, w_i, Y_i\}_{i=1}^I, Y, C)$ by dividing them by e^{gt} . We denote transformed variables by placing a carat over them.

This transformed system of equations is given by (3.1) – (3.16)

$$z_A' = \rho_A z_A + e_A'; e_A' \sim iid(0, \sigma_A^2) \quad (3.1)$$

$$z_R' = \rho_R z_R + e_R'; e_R' \sim iid(0, \sigma_R^2) \quad (3.2)$$

$$1 = \beta E \left\{ e^{z_R'} \left(\frac{\hat{C}^{(1+g)}}{\hat{C}} \right)^{-\sigma} (1 + r' - \delta) \right\} \quad (3.3)$$

$$p_i \hat{Y}_i (1 - x_i) = a_i \hat{Y} \quad (3.4)$$

$$r_i \phi_i^K \hat{K} = b_i p_i \hat{Y}_i \quad (3.5)$$

$$\hat{v}_i \phi_i^N \bar{N} = c_i p_i \hat{Y}_i \quad (3.6)$$

$$\hat{w}_i \bar{L}_i = (1 - b_i - c_i) p_i \hat{Y}_i \quad (3.7)$$

$$\hat{Y}_i = (\phi_i^K \hat{K})^{b_i} (e^{z_A} \phi_i^N \bar{N})^{c_i} (e^{z_A} \bar{L}_i)^{1-b_i-c_i} \quad (3.8)$$

$$1 = \sum_i \phi_i^K \quad (3.9)$$

$$1 = \sum_i \phi_i^N \quad (3.10)$$

$$\hat{C} = \hat{Y} + (1 - \delta) \hat{K} - (1 + g) \hat{K} \quad (3.11)$$

$$r_i = r \quad (3.12)$$

$$\hat{v}_i = \hat{v} \quad (3.13)$$

$$\hat{Y} = \sum_i p_i \hat{Y}_i \quad (3.14)$$

$$\prod_i \left(\frac{a_i}{p_i} \right)^{a_i} = 1 \quad (3.15)$$

$$x_j = 0; j \in \text{nontraded} \quad (3.16a)$$

$$p_k = q p_k^*; k \in \text{traded} \quad (3.16b)$$

Equations (3.1) – (3.16) are a system of dynamic equations which can be calibrated to produce a desired steady state. The steady state solution can be found by replacing the values of all the variables in this system with their steady state values. Equations (3.9) – (3.16) can be used as definitions. Equations (3.1) and (3.2) imply the steady state values of the shocks are zero. This reduces the system to (3.3) – (3.8); a system of fifteen equations in fifteen unknowns, $\bar{K}, \bar{q}, \{\bar{x}_j\}_{j \in \text{traded}}, \{\bar{p}_k\}_{k \in \text{nontraded}}, \{\bar{\phi}_i^K, \bar{\phi}_i^N\}_{i=1}^{I-1}$. This system might possibly be solved algebraically, but we choose to solve it numerically instead.

4. Baseline Calibration and Description of the Steady State

We have the following set of parameters for which we need numerical values if we are to solve and simulate our model. The set is $\beta, \delta, \sigma, g, \{a_i, b_i, c_i, \bar{L}_i\}, \bar{N}, p_{k \in \text{traded}}^*$.

δ is the depreciation rate and is set to the average of the observed ratio of depreciation reported by the IMF to a capital stock measure constructed by the perpetual inventory method

from IMF real investment data. We use the period 1955 – 2003 and we use 1960 – 2008 for Korea.

g is the annual growth rate of technology, which we set to the average value of the Solow residual for each country over roughly the past twenty years³.

β , β (the subjective discount factor) and σ (the intertemporal elasticity of substitution) are linked via the steady state version of equation (3.3), $1 = \beta(1 + g)^{-\sigma}(1 + \bar{r} - \delta)$. We set σ to 1 and choose a value for which β which implies an annual real net return on capital equal to the ex post real return⁴.

The values for the sector shares in GDP (the a_i 's) come from the GTAP6 database. We rely on the publicly available summaries of the database which aggregate industries into ten broad categories. We further aggregate these into five groups: agriculture, extraction, manufacturing, traded services, and non-traded services. We define the agriculture industry as any of the GTAP industries that use land as a factor of production. Similarly, extraction is any industry that uses natural resources. For these two industries only we modify our production function in equation (3.8) to include a fourth factor, which we interpret as either land or natural resources.

$$\hat{Y}_i = (\phi_i^K \hat{K})^{b_i} (e^{z_A} \phi_i^N \bar{N})^{c_i} (e^{z_A} \bar{T})^{d_i} (e^{z_A} \bar{L}_i)^{1-b_i-c_i-d_i} \quad (4.1)$$

We set the stock of land (\bar{T}) and natural resources (\bar{R}) both to 100 via normalization of units.

To obtain numerical values for the a_i 's we take the ratio of total value-added on goods in that sector to total value-added on all goods.

We also calculate the b_i 's, c_i 's and d_i 's, by taking the total compensation reported for each factor in that industry as a percentage of the value-added on the good.

For labor endowments we set the total endowment of labor to 100 by normalization. We obtain the relative amounts of unskilled labor and skilled labor by using data from the International Labor Organization and matching these to our five sectors as closely as possible.

To obtain international prices we use export shares for each of our industries as calculated from the GTAP data. We then solve for the steady state of our model using

³ 1986 – 2003 for Japan and 1986 – 2008 for Korea.

⁴ 1.88% in Japan and 4.46% in Korea.

international prices as variables and export shares as long-run steady state values. When simulating our model we treat the prices of traded goods that we find this way as fixed parameters.

The values of all parameters are reported for both Japan and Korea in table 1.

To determine which industries can be best classified as non-traded we sum the value of exports and imports and divide by value-added for that industry. If this number is less than 5% we classify then industry as non-traded. By this criterion only one industry, non-traded services, is not a tradable good, in both Japan and Korea.

5. Steady States of Various Policy Options

We consider relaxation of immigration constraints by imagining a policy that allows the labor endowment of the economy to rise by some fixed percent. We view foreign and domestic labor as perfect substitutes as long as the labor is of the same type. A policy maker can choose to relax or constrain immigration in general which would alter the supplies of all labor. Or the policy maker could target particular types of labor, and leave endowments of the other types unchanged.

As figure 1 shows, the percentage of foreign residents to the total population is quite low in Japan and Korea compared to other developed countries. In Japan this number was 1.63% in 2006 and in Korea it was 0.53% in 2002.⁵ By contrast, these numbers were 11.71% for the United States in 2003 and 8.81% for Germany in 2006. We consider a change in immigration policy that raises the percentages in Japan and Korea from their current values to 9.50%⁶

The policies we consider differ in the types of labor allowed to immigrate.

1) We first consider a case where only unskilled labor is allowed to immigrate. In Japan this leads to an increase in the unskilled labor force of 11.15% and in Korea, 12.30%.

2) Secondly, we consider a case where both skilled and unskilled labor are allowed to immigrate in the same proportions of the current labor force. In Japan this leads to an increase in all types of labor of 9.14% and in Korea of 10.22%.

⁵ These are the most recent years for which data is available from the ILO.

⁶ Roughly the average of the US and Germany over the past 20 years.

3) Third, we consider a case where both types of labor can immigrate, but skilled labor is given a priority. We allow equal numbers of workers of both types to enter the country, but since there are more unskilled workers in the workforce already, this leads to smaller percentage increases for unskilled labor. For Japan unskilled labor rises by 5.57% and skilled labor rises by 25.44%. For Korea the increases are 6.15% and 30.30%, respectively.

4) A fourth scenario is to allow only skilled labor into a country. For Japan we increase all stocks of skilled labor by 50.88% and in Korea they increase by 60.59%.

5) For a fifth case we consider allowing skilled labor from only the non-traded services sector to immigrate. In both countries this is the sector that employs the most skilled labor. In Japan this leads to an increase of L_5 by 86.03% and in Korea it rises by 91.31%.

6) Finally, we allow skilled labor from only the traded services sector (the second largest employer of skilled labor) to immigrate. This causes an increase in L_4 in Japan of 424% and an increase of 416% in Korea.

The steady state values for the baseline case and for the six different immigration cases are presented in tables 2 & 3.

Several interesting patterns emerge from these tables.

First, increases in skilled immigration lead to greater increases in capital, output and consumption than increases in unskilled immigration. In both countries, the ranking in terms of output increases from lowest to highest is unskilled only, then proportional, then equal, and then skilled only. This ordering corresponds to greater proportions of skilled labor new immigration.

Second, the highest gains in output and consumption come from targeting skilled labor in the traded services sector. This is true in both countries.

Third, as the mix of immigration moves from unskilled to skilled labor, skilled wages fall and unskilled wages rise.

Fourth, not surprisingly, increases in immigration specific types of skilled labor lead to a drop in the wages of that labor.

Fifth, an increase in nontraded services labor causes the wages of all other types of labor to rise, while an increase in traded services labor causes wages in agriculture, extraction, and manufacturing to fall.

All these results are for the steady state, to which the economy will trend in the long. However, the long-run can be very far in the future and policy makers may well be interested in changes in output, consumption and wages along the transition path to this new steady state.

We now turn to these transition paths.

6. Solving for the Model's Dynamics

We use the method of undetermined coefficients to find linear approximations to the transition functions for the endogenous state variables in our model. Christiano (2002) and Uhlig (1999) discuss this method in detail.

We define four sets of variables from the system in equations (3.1) – (3.16). First are the exogenous state variables. We assign these to a vector \mathbf{Z}_t as shown in (5.1).

$$\mathbf{Z}_t \equiv [z_A \quad z_R] \quad (5.1)$$

Similarly, we put the log deviations of the endogenous state variables from their steady state values into a vector \mathbf{X}_t . We denote log deviations of variable with a tilde. There is only one of these, and we alter the timing so that capital chosen for production next period is part of vector \mathbf{X} now.

$$\mathbf{X}_t \equiv [\tilde{K}'] \quad (5.2)$$

We also define a set of endogenous non-state variables that cannot be easily solved as functions of the state variables. Uhlig (1999) refers to these as “jump” variables. We put these log-deviations into a vector \mathbf{Y}_t .

$$\mathbf{Y}_t \equiv [\tilde{q} \quad \tilde{p}_1 \quad \hat{p}_2 \quad \tilde{p}_3 \quad \tilde{p}_4 \quad \hat{p}_5 \quad \tilde{\phi}_1^K \quad \tilde{\phi}_2^K \quad \tilde{\phi}_3^K \quad \tilde{\phi}_4^K \quad \tilde{\phi}_1^N \quad \tilde{\phi}_2^N \quad \tilde{\phi}_3^N \quad \tilde{\phi}_4^N] \quad (5.3)$$

Lastly, we solve equations (3.4) – (3.11) & (3.14) to define a set of definition variables that are functions of the vectors $\mathbf{X}_{t-1}, \mathbf{X}_t, \mathbf{X}_{t+1}, \mathbf{Y}_t, \mathbf{Y}_{t+1}, \mathbf{Z}_t$ & \mathbf{Z}_{t+1} .

Using these definitions we can construct linear approximations of equations (3.12), (3.13), (3.15) & (3.16) of the form shown in equation (5.4).

$$\mathbf{A}\mathbf{X}_t + \mathbf{B}\mathbf{X}_{t-1} + \mathbf{C}\mathbf{Y}_t + \mathbf{D}\mathbf{Z}_t = 0 \quad (5.4)$$

Similarly, an approximation of (3.3) yields equation (5.5).

$$\mathbf{F}\mathbf{X}_{t+1} + \mathbf{G}\mathbf{X}_t + \mathbf{H}\mathbf{X}_{t-1} + \mathbf{J}\mathbf{Y}_{t+1} + \mathbf{K}\mathbf{Y}_t + \mathbf{L}\mathbf{Z}_{t+1} + \mathbf{M}\mathbf{Z}_t = 0 \quad (5.5)$$

Lastly, equations (3.1) & (3.2) can be written as equation (5.6).

$$\mathbf{Z}_{t+1} = \mathbf{N}\mathbf{Z}_t + \boldsymbol{\varepsilon}_{t+1}; \boldsymbol{\varepsilon}_{t+1} \sim iid(\mathbf{0}, \boldsymbol{\Sigma}) \quad (5.6)$$

The derivative matrices in equations (5.4) and (5.5) can be found algebraically, or they can be found using numerical methods.

Both Christiano (2002) and Uhlig (1999) show how this system can be solved for linear transition functions for the endogenous state variables and jump variables as expressed in (5.7) & (5.8).

$$\mathbf{X}_t = \mathbf{P}\mathbf{X}_{t-1} + \mathbf{Q}\mathbf{Z}_t \quad (5.7)$$

$$\mathbf{Y}_t = \mathbf{R}\mathbf{X}_{t-1} + \mathbf{S}\mathbf{Z}_t \quad (5.8)$$

Given starting values for \mathbf{X}_0 and \mathbf{Y}_0 , these two equations can be used in conjunction with (5.6) and a random number generator to simulate a series of deviations of variables from their steady state values over any arbitrarily long history. Once these deviations are known for every period we can recover the stationary values for each period using equation (5.9)

$$\hat{x}_t = \bar{x}e^{\tilde{x}_t} \quad (5.9)$$

Finally, we can construct non-stationary time-series for these variables by adding back the growth component that was removed in section 3.

$$x_t = \hat{x}_t e^{gt} \quad (5.10)$$

7. Non-Stochastic Simulations of Transition Paths

We examine the transition of our model economy from the current steady state to a new one by using the simulation methodology discussed in section 5. We set all exogenous shocks to zero to focus on the endogenous dynamics. We assume our economy is initially in the steady state, meaning that $\mathbf{X}_t = 0$. This will cause the economy to remain in the steady state until something changes. When policy is changed in period T , the economy will have a new steady. We set the value of \mathbf{X}_t in this period to $\mathbf{X}_T = \bar{K}_{old} / \bar{K}_{new}$. From this point in time on, the economy will slowly converge to the new steady state, its dynamics driven by the \mathbf{P} matrix in equation (5.7).

Figure 4 shows a typical transition. In this case it is for Japan with an increase of skilled immigration only. Notice that in addition to the long-run changes in steady state values, these transition paths show immediate effects. For example, the increase in skilled labor (which is assumed to happen immediately) causes immediate increases in output of all intermediate and

final goods, as well as consumption. It also has immediate effects on exports and factor prices. After these immediate effects, the economy slowly transitions to a new steady state as the capital stock adjusts slowly over time. In some cases the upward jump is followed by additional increases over time; as in the case of outputs and consumption. In other cases, however, the initial jump overshoots the new steady state value and the variable returns partway (exports and skilled wages) or all the way back (the interest rate) to the original value.

We report only this one example because we are interested in augmenting these transition paths with confidence bands.

8. Monte Carlo Simulations of Transition Paths

Transition paths like those from the preceding section can be misleading because they show the effects of a change in steady state while assuming there are no exogenous shocks. Since the shocks are, on average, zero this is an unbiased prediction. It gives no sense of the amount of variation from this average one should expect, however. It is useful to have some sort of confidence band around these average predictions.

To do this we conduct a series of Monte Carlo simulations. We proceed as described in section 7, but generate non-zero series for ϵ_t using a random number generator. In our case we assume that the two elements of ϵ_t are distributed as normally and independently from each other. The variance of each series is chosen to generate volatility of output that matches time-series data on real GDP from the country in question. For each case we run 1000 Monte Carlo simulations and report the upper and lower 95% confidence bands for each time horizon from this set of simulations. We also report standard error bands by adding and subtracting two standard deviations at each time horizon. Both methods yield almost identical results.

Figure 5 examines the same case as figure 4. The difference is that we have added the deterministic trend back to all growing series and report the confidence and standard error bands. These graphs are the type of predictions a researchers would ideally provide to policy maker. That is, an average forecast of the likely effects of immigration reform, along with some feel for the uncertainty associated with these forecasts.

Figures 5 – 16 report transition paths for both Japan and Korea under each of the six immigration policies discussed in section 5. These figures confirm many of the steady state results discussed in section 6. However, there are some additional findings worth mentioning.

First, there is a great deal of uncertainty surrounding the time paths of almost all the time series. Only export shares show changes that are significantly different from the previous steady state over the 40 years shown.

Second, for stationary time series, like export shares & the interest rate, the immediate adjustments to larger workforces are often much larger than the gradual adjustments to the new steady state that follow. For non-stationary series, the short-run jumps are much smaller in percentage terms because of the effects of long-run growth.

Third, regardless of the variable there is a great deal of inertia in the transition to the new steady state. Interest rates, for example, take more than twenty years to return close to their initial levels.

9. Conclusions

This paper has examined the effects of immigration liberalization in Japan & Korea. Both these countries have foreign populations that are quite small compared to economies of similar size and level of development. We have calibrated a DSGE model of a trading economy and considered the effects of six different policies which bring the percentage of the population that is foreign to roughly the same levels as are observed in Germany or the US. Because we have modeled growing economies, the immediate effects of increased immigration are relatively small compared to long-run increases due to economic growth. Effects on exports are much more dramatic in the short run. We have shown that immigration reforms which targets skilled workers leads to greater welfare gains than those which allow in more unskilled labor.

Our model is one of a small trading economy. For technical reasons we have built a model where international borrowing and lending is not allowed and trade balances each period. Small open economy DSGE models require some sort of friction to international movement of physical capital in order to avoid immediate adjustments of the capital to a new steady state in the face of shocks to the economy. Our setup, where final goods are not traded and only some of the intermediate goods used to produce them are, should have a similar type of friction.

However, since we use standard log-linearization techniques and linearize about the model's steady state, the linear approximation of this adjustment cost is zero and the resulting dynamic equations used in the simulation are unstable.

Related work inspired by this shortcoming⁷ should make it possible to simulate such a model with better approximations of the adjustment cost away from the steady state. Assuming these technical difficulties can be overcome; a much more interesting model with international borrowing and lending and with repatriation of wage income by foreign workers could be built and simulated. Sadly, we must leave such a model for future research.
