Cooperative and non-cooperative solutions to carbon leakage

Abstract

In this paper we develop a modified version of the computable general equilibrium GTAP-E model in order to assess potential economic and carbon emissions effects related to alternative policy measures implemented with the aim of reducing carbon leakage. We compare two approaches to dealing with carbon leakage: a cooperative solution, where all countries cooperate to achieve Kyoto targets without carbon leakage through a global carbon market, and a non-cooperative solution, where Annex I countries introduce carbon tariffs in order to solve the carbon leakage problem unilaterally. Alternative carbon tariff hypotheses are compared. On the one hand, carbon tariffs could be exogenously determined according to the domestic carbon tax level applied by Annex I countries. On the other hand, carbon tariffs could be endogenously computed according to alternative policy goals: CO₂ emissions abatement targets for Non-Annex I countries or maintaining the international competitiveness of Annex I countries' firms. Results provide evidence on the scarce effectiveness of carbon tariffs both in reducing carbon leakage and enhancing economic competitiveness. On the contrary, these tariffs seem to have potentially large negative welfare effects not only on the Non-Annex countries, but also on some Annex I countries.

1. Introduction

In recent years, a large body of the international literature as well as policy debate has expressed increasing interest in measures to mitigate the negative externalities of climate change policies. As a matter of fact, the imposition of stringent climate policies may produce substantially distortive effects in terms of displacement and re-allocation of carbon intensive productive processes in countries where no climate policies are in action, a phenomenon also known as the carbon leakage effect (OECD, 2006). However, the extent of carbon leakage is controversial and there is considerable debate on the design of the correct policy mix to reduce it.

Generally speaking, the potential outcome of unilateral climate change policies may be an increase in relative comparative advantages of non-compliant countries, or in other words, a competitiveness loss on the international markets faced by abating countries. Consequently, some forms of border adjustments have been invoked in order to restore a level playing field between domestic producers facing abatement policies (e.g., carbon tax or emission trading) and foreign exporters subject to a carbon tariff (Moore, 2010; Wooders and Cosbey, 2010).

The jury is still out on the exact design and practical implementation of these adjustments since there are several unresolved issues. In this respect, we will elaborate on the existing studies and provide further evidence of the extent to which different forms of Carbon Border Tax (CBT) may effectively reduce carbon leakage and preserve the international economic competitiveness of domestic firms in compliant countries. However, the major focus of the paper is on the ambiguities regarding the possible goals to be achieved through CBTs. Indeed, carbon tariffs are often justified both as instruments for reducing the leakage rate or restoring the competitiveness of domestic firms: our results show that the two goals are not necessarily consistent.

We develop a modified version of the computable general equilibrium GTAP-E model (McDougall and Golub, 2007) in order to assess potential economic and carbon emissions effects related to CBT adjustment schemes. Our regional aggregation includes the 11 Annex I countries/regions featuring country-specific CO₂ reduction commitments listed in the Kyoto Protocol and the largest emerging economies within the Non-Annex list, including Brazil, China, India and Mexico, that are expected to be the most likely source of carbon leakage.

In terms of sectoral aggregation, we distinguish 21 sectors in order to simulate the impact of alternative policies in energy intensive and non-intensive sectors. We replace some of the substitution elasticities regarding energy goods using the most recent estimates available in the literature, since the elasticity parameters play a crucial role in influencing

the supply and demand of fossil fuels. Indeed, our results show that leakage rates are extremely sensitive to these parameters. Finally, we update the GTAP 7.1 database by creating a 2012 baseline on which we impose the Kyoto objectives for all Annex I countries, assuming that the Kyoto Protocol is not affected by low coverage problems.

In order to build a benchmark for the assessment of the effectiveness of CBT alternative policies, we first assess the carbon leakage implied by the Kyoto agreement featuring domestic carbon taxes in two scenarios with and without emission trading.¹ In the case of emissions trading, carbon dioxide emission permits can be traded exclusively among Annex I countries: this is consistent with the provisions of the Kyoto Protocol even if they have not been implemented yet. We then compare possible approaches of dealing with the carbon leakage arising from emission trading through different carbon tariff schemes (non-cooperative scenarios) with a cooperative scenario featuring global emission trading where Non-Annex countries also play an active role.

In the non-cooperative scenarios, carbon tariffs are either based on the domestic carbon tax or endogenously computed as *ad valorem* equivalents. In the former case, a specific carbon tariff is computed by multiplying the carbon tax either by the actual carbon content of imports or by the carbon content of the corresponding domestic good. In the latter case, the *ad valorem* tariff equivalent is set either with the aim of eliminating (or at least reducing) carbon leakage or with the aim of keeping the competitiveness of Annex I countries in the international markets unchanged.

By applying the exogenously given CBT based on the domestic carbon tax, we assess the economic impacts of the unilateral policies that are presently discussed in the political debate especially in the European Union. The effects produced by an exogenous carbon tariff on competitiveness, welfare changes and emission levels of Non-Annex countries are compared with those resulting from 'endogenous tariffs' (i.e., tariffs computed in order to achieve a given objective either in terms of leakage or competitiveness). The distance between the exogenous and the endogenous carbon tariffs gives an idea of the distance between the policy schemes actually discussed and the motivations put forward by the proponents of these policies.

On the other hand, we implement a cooperative scenario where Annex I countries face their emissions targets as defined in the Kyoto agreement whereas Non-Annex countries

¹ In this paper, we follow a standard assumption in the literature using applied general equilibrium models, namely that all abating policies may be expressed in monetary values by computing a domestic carbon tax applied to fossil fuels consumption. When we assume the existence of an emission trading system, the carbon tax at equilibrium equals the permits price. We are aware of the existence of a more complex policy mix adopted in many countries, but for the aim of this paper we are only concerned with the relative incidence of the compliance costs.

face a zero-increase in emissions constraint. Results from this zero-leakage scenario are compared with the economic and environmental effects resulting from alternative policies applied unilaterally by Annex I countries. Such a comparison highlights the advantage for Non-Annex countries of maintaining their conservative position in the climate negotiations or not.

The rest of the paper is structured as follows. In Section 2 we provide a literature review on carbon leakage and border adjustments. In Section 3 we describe the model, the 2012 baseline and the non-cooperative and cooperative scenarios. Section 4 presents the main simulation results and Section 5 provides some final remarks.

2. The carbon leakage issue

2.1 The measurement of carbon leakage

A global solution to combating climate change has not been implemented yet, since the output of Copenhagen meeting (2009) was a non-binding agreement. Cancun negotiations (2010) represented a step forward for reaching a cooperative solution, but global international cooperation for fighting climate change still seems a difficult goal to be achieved. For this reason, policy actions to mitigate climate change and reduce emissions still remain unilateral. It has already been noted that the efficiency of CO₂ reduction policies could be undermined by the presence of carbon leakage (Hamasaki, 2007). The use of economic instruments for greenhouse gas (GHG) emission reduction with a non-global approach is likely to have negative impacts on the international competitiveness of some industrial sectors, for example, the steel and the cement sectors (OECD, 2003, 2005). If only a few countries are involved in the implementation of climate change policies, non-abating countries may have comparative advantages in producing and exporting energy intensive goods with the risk that the efforts of abating countries are lost. Veenendaal and Manders (2008), for instance, point out that if a coalition of countries committing themselves to reducing GHG emissions remains limited in its coverage, carbon leakage is likely to occur, partly offsetting the reduction efforts made by the coalition. The vast and growing literature on this issue distinguishes two typologies of leakage: the first one is caused by a shift in the location of production towards non-compliant regions and the second one is related to an increase in energy consumption in non-abating regions due to the lower prices resulting from the reduced demand for fossil fuels on the international markets by abating countries.

The imposition of stringent climate policies in selected countries may produce

substantially distortive effects in terms of displacement and re-allocation of carbon intensive productive processes in countries where no climate policies are in action, in a well consolidated literature strand referring to the so-called pollution haven effect (Copeland and Taylor, 2004). The pollution haven hypothesis explains the first type of leakage where carbon/energy intensive firms will move from abating countries to non-abating countries in order to exploit relative comparative advantages arising from heterogeneous environmental standards.

Carbon leakage due to production relocation is related to the fact that leakage increases with the intensity of international competition in energy-intensive goods. If this competition is strong and energy intensive goods are perfectly substitutable in terms of production location, this will bring production of carbon intensive goods to countries with lower energy costs. In other words, when countries have different environmental regulatory stringency, production will be located where environmental costs are lower. As emphasized by Babiker (2005), in extreme situations where energy-intensive goods produced in different countries are perfectly homogeneous, the relocation of the production of carbon intensive goods to non-abating countries is almost complete, leading to carbon leakage rates that can even exceed 100%.

In addition to the leakage resulting from a shift in production location, a second type of leakage could result from a substitution effect induced by decreasing carbon-energy demand in the abating countries and the consequent fall in international energy prices (Gerlagh and Kuik, 2007). The energy market model explains the second type of carbon leakage. The reduction in fossil fuel demand in abating countries leads to lower prices on the world energy markets, which in turn fosters energy demand in non-abating countries (Burniaux and Oliveira Martins, 2000; Felder and Ruherford, 1993).

In a scenario with emission targets achieved by a carbon tax, there may be a lower incentive to relocate production to non-abating countries, and the cause of leakage switches to the second type where the increase in demand from non-taxing countries is higher than the reduction in energy demand from taxing countries (Elliot *et al.*, 2010b). As a matter of fact, the magnitude of the taxing countries' energy demand combined with the elasticity of the energy supply curve are key drivers in determining different types of leakage (Kuik and Gerlagh, 2003). According to Gerlagh and Kuik (2007), the energy market model seems to be the prevalent explanation of carbon leakage estimates from simulation analyses. It is also worth noting that this is the only available mechanism in all models where international reallocation of factor endowments is not allowed, such as the static GTAP-E used in this paper.

The rate of carbon leakage is usually computed as the ratio between the increase of CO₂ emissions in non-abating countries and the reduction of CO₂ emissions in countries implementing GHG abatement policies. As reported by the Energy Modeling Forum (2000) and Kuik and Verbruggen (2002), carbon leakage rates vary widely according to the model used: 5% (GREEN), 8% (G-Cubed), 9% (GTEM), 11% (Gemini-E3), 14% (WorldScan), 26% (MS-MRT), 34% (MERGE4).

In addition to these macro leakage rates, sectoral leakage rates can be computed as the ratio of the additional emissions in each productive sector of Non-Annex I countries to the emission reduction achieved in Annex I countries in the same sector (Kuik and Ofkes, 2010). Sectoral rates are useful for understanding which sectors are most responsible for the leakage rate and which should consequently be targeted by specific trade policy measures.

Even if the implications for international trade of emission abatement policies are crucial, especially when considering their acceptability and feasibility, few studies have adopted a global approach when trying to quantify simultaneously the effects on emissions, sectoral exports and output of all countries, as well as distributional welfare effects at country level.

Babiker and Jacoby (1999) use the EPPA-GTAP model and find a global leakage rate of 6%: 30% of the leakage is related to China alone and more than 60% to only five countries: Brazil, China, India, Mexico and South Korea. McKibbin *et al.* (1999) use the G-Cubed general equilibrium model and focus on the effects of the tradable emissions permit system proposed in the Kyoto Protocol on international trade and capital flows. Their results show a significant carbon leakage effect. Initially, over half of this leakage is due to the lower oil demand from Annex I countries, and in particular from the US, and the fact that non-abating countries buy and burn more oil. In the long run, it is economic growth that produces most of the increase in Non-Annex emissions. Bernstein *et al.* (1999) adopt the dynamic general equilibrium model MS-MRT and find that significant leakage occurs when there is no international permit trading. It is mainly associated with fuel substitution due to lower fuel prices in developing countries and it diminishes when Annex I emission trading is allowed.

In the analysis developed by Haaparanta *et al.* (2001) using a modified GTAP-E version, the leakage rate also decreases when emission permit trading is allowed between Annex I countries compared to the case where Kyoto targets are only introduced on a national basis. This result is mainly due to the crucial role played by the Former Soviet Union (FSU), where emissions increase by 3.2% in the scenario with domestic implementation whereas

with emission permit trading, they are dramatically reduced by almost 60%.² Among the factors that potentially affect carbon leakage, little attention has been paid to changes in import tariffs. Kuik and Verbruggen (2002) compare a scenario where emissions of Annex I are constrained to the Kyoto objectives with no change in import tariffs and a similar one in which tariffs are adjusted to implement the Uruguay Round and find that the leakage rate increases with trade liberalization.

Carbon leakage estimates seem to be very sensitive to different model settings. Two key parameters emerge as the driving factors of highly heterogeneous leakage rates: the Armington elasticities in the import demand module and the substitution elasticities in the energy nests of the production module (Gerlagh and Kuik, 2007). In particular, if lower Armington elasticities values are assumed, there will be fewer opportunities for Non-Annex countries to expand their exports towards compliant countries thus resulting in lower leakage (McKibbin *et al.*, 1999). Moreover, as a consequence of price impacts of emission reduction targets, non-abating countries will import less carbon-intensive commodities from Annex I countries due to changes in their comparative advantages. At the same time, given a certain value of Armington elasticities, non-abating countries will easily substitute imported intermediates from Annex I countries with intermediates from other non-abating countries and substitute aggregate imports with domestic intermediates (Wang *et al.*, 2009) eventually producing a demand-driven leakage effect. In this respect, higher substitution elasticities in the production function between energy and other inputs, as well as between alternative fossil fuels, would lead to larger drops in world energy price and hence to larger leakage rates (Kuik, 2001).

Gerlagh and Kuik (2007) perform a meta-analysis on the determinants of the leakage rate by comparing 17 studies and working with CGE models in order to investigate the relative importance of alternative driving factors of this phenomenon. A major role in explaining leakage rates seems to be played by the elasticity of energy supply and Armington elasticity of energy-intensive goods. These elasticities together explain 42% of the variation in the leakage rate. They also show that carbon leakage is negatively related to the elasticity of energy supply and positively related to Armington elasticity. These findings tend to support the pollution haven hypothesis rather than the energy market model.

2.2 *Alternative carbon border tax designs*

Positive analysis on the existence and potential causes of the carbon leakage effect paved the

² This result remains valid only in the case where hot air is not included among total emissions of transition economies.

way for a growing strand of literature dealing with policies that could solve the problem. We can provide a real-world example: European energy-intensive sectors, facing a price for carbon emissions, could be at a competitive disadvantage compared with regions with a less stringent, or inexistent, climate policy and they are exposed to negative effects in terms of loss of production and jobs. With the aim of restoring competitive fairness and preventing carbon leakage, CBTs could then be introduced.

Abating countries may decide to impose two forms of CBT: full or partial adjustment. Full adjustment refers to a carbon tariff (in other words, a carbon border tax) applied to imported goods from non-compliant countries plus a tax rebate for domestic goods which are exported.³ Partial adjustment refers to the application of border carbon tariffs without rebates on exports (Fischer and Fox, 2009). For example, in the European Union, since it is a net exporter of energy-intensive products, a refund on exports is a more effective means of supporting employment in sectors covered by the Emission Trading System (ETS) than a levy on imports (Veenendaal and Manders, 2008).

There is growing concern over CBT as a feasible and effective unilateral policy measure for preventing carbon leakage. In particular, three major issues arise from the international literature. The first is how to design a CBT which is consistent with WTO rules, feasible in its implementation, and fair from the point of view of the heterogeneous exporting countries facing the carbon tariff. To this purpose, there is an open debate on the possibility of designing CBT adjustments consistent with WTO rules, since import tariffs may be illegal under international trade law. Because of the legal uncertainty, a CBT regime will be controversial and probably lead to a number of disputes between WTO countries (Messerlin, 2010; Moore, 2010; Wooders and Cosbey, 2010), but we will not be dealing with this issue in this paper.

While the vast majority of scientific and political documents agree on the value of the specific tariff which should be taken as equivalent to the specific carbon price in the abating countries (i.e., equal to the domestic carbon tax or to the net equilibrium permits price if an emissions trading scheme is allowed), there are different opinions about how to quantify the embedded carbon in traded goods from non-compliant countries.

Two alternative computation methods are often proposed (Elliot *et al.*, 2010a,b). The first one is to apply a best available technology (BAT) in the importing country where the carbon content for each good produced in the compliant countries is applied to imported goods coming from non-abating economies. The second one considers the effective carbon content of the imported goods, thus relying on the production technique applied by the producing

³ In the rest of the paper, the terms “carbon tariff” or “carbon border tax” will be used interchangeably.

country. This second method could introduce a high degree of uncertainty for exporting countries and lead to a heterogeneous treatment and a relative penalty for less developed economies.

Moreover, the two computation methods may be applied twofold: if a direct approach is considered, only carbon emissions related to the production process are accounted for. If an indirect accounting approach is implemented, all CO₂ emissions related to the production process of all intermediates are considered for the application of the CBT, leading to substantially higher implementation difficulties (Atkinson *et al.*, 2010).

The second question concerns the effectiveness of CBT in preventing carbon leakage (Schenker and Bucher, 2010). As a matter of fact, empirical analyses provide contrasting results on the effective capacity of CBTs to reduce emissions from non-abating countries, depending both on model settings and alternative CBT designs. For example, Mattoo *et al.* (2009) show that carbon leakage is a very limited phenomenon, while introducing a CBT based on the carbon content of imports would seriously damage Non-Annex trading partners. Such an action would impose average tariffs on merchandise imports from India and China of over 20 percent and would lower manufacturing exports of these countries towards Annex I by between 16 and 21 percent. On the contrary, Dong and Whalley (2009) simulate CBTs based on the emissions generated by comparable domestic production in the importing country (BAT approach). In this case CBTs effects are generally small, depending on the emission targets of abating countries, and CBTs contribute to alleviating the carbon leakage effects.

Adopting a sector-based approach, the picture changes again. Kuik and Hofkes (2010) explore the implications of CBTs on the EU ETS, distinguishing between sectoral and macro rate of leakage. In this case, CBTs impose significant reductions in sectoral leakage rates and more modest ones in the macro leakage rate. This is due to the fact that CBTs preserve sectoral competitiveness in abating countries but do not directly affect the leakage driven by the fall in energy prices and the substitution effect which accounts for the largest part of the macro rate of leakage. The results of this study clearly show how CBTs are not very effective from an environmental point of view.

Finally, choosing the indirect emission accounting approach strongly affects carbon leakage estimates. Atkinson *et al.* (2010) analyse the embodied carbon emissions in goods produced and consumed by different countries, combining the GTAP model with both the Bilateral Trade Input-Output (BTIO) and Multi-Region Input-Output (MRIO) approaches. They find that the carbon tariff equivalent to a carbon price of 50\$ per ton of CO₂ amounts to 10% of the value of the average export bundle of non-abating countries, but tariffs may be

two to three times higher for specific sectors. This suggests that CBTs risk being trade distorting and being associated with losses in efficiency and welfare, particularly in low and middle income countries.

A third issue relates to welfare implications of a CBT approach. The degree of political acceptance of a policy is very likely to depend on its perceived “fairness” in terms of welfare changes for the different economic agents or countries affected by its implementation (OECD, 2006). It is worth noting that CBTs clearly represent a second best solution compared with the implementation of global climate policies which would establish a similar carbon price for all countries (Stern, 2006).

To sum up, several contributions analyse the carbon leakage issue, address its effects on competitiveness or emission levels and investigate the different options for designing CBT adjustments and their compatibility with WTO rules. Nonetheless, less attention has been paid to the issue of consistency between different goals such as enhancing competitiveness and reducing carbon leakage. To this end, we will compare standard specific carbon tariffs based on domestic carbon tax (or permits price), with two endogenously determined CBTs. The first one will be designed as the equilibrium carbon tariff which preserves the competitiveness of compliant countries whereas the second one will be explicitly designed to make the carbon leakage rate disappear (see par. 3.3 for details).

3. Model and Scenario Setting

3.1 Model description

The Computable General Equilibrium GTAP-E model is an energy-environmental version of the standard GTAP model specifically designed to simulate GHG emissions mitigation policies. It includes an explicit treatment of energy demand, the possibility of inter-factor and inter-fuel substitution, information on carbon dioxide emissions accounting and the possibility of introducing market-based policy instruments such as carbon taxes or emissions trading (Burniaux and Truong, 2002; McDougall and Golub, 2007).

As far as the production structure is concerned, GTAP-E adds several substitution nests such as between a capital-energy composite and other production factors or between capital and a energy-composite where the latter is obtained by substitution across different energy commodities.

Carbon taxation is modelled with different tax wedges for firms, private and government consumption of domestic and imported energy products. An international trading of

emissions (IET) scheme, as described in Article 17 of the Kyoto Protocol, is modelled by defining bloc-level emissions and emissions quotas compared with the abating (Annex I) countries. Carbon dioxide emission permits can be traded in an international market which can only be accessed by compliant countries to buy or sell permits. Accordingly, once Kyoto targets for each Annex I country are established, the model computes the carbon tax required to reach these emission reduction objectives. The carbon tax represents the marginal cost of abatement equalized between regions that participate in IET and at equilibrium coincides with the permits price. If emission trade is not allowed, the carbon tax represents the domestic cost of abatement in each Annex I country. If we consider the GTAP-E structure, the carbon tax reduces CO₂ emissions by augmenting the cost of fossil fuels as inputs in the production and consumption functions (for firms and private households, respectively).

In this paper, we introduce some changes in the GTAP-E model. First of all, some substitution elasticities - namely the substitution elasticity between the capital-energy composite and the other endowments and the substitution elasticity between capital and energy in all the nests related to the energy composite - were replaced with those proposed by Beckman and Hertel (2010). The Armington elasticities were also changed as in Hertel *et al.* (2007).⁴ This specific choice allows us to investigate features related to carbon leakage more closely since the literature agrees on the crucial role of substitution elasticities in the quantification and geographical distribution of leakage rates.

A second set of changes refers to the data. We updated the GTAP-E dataset using the latest version of the GTAP Database version 7.1 (base year 2004) as well as the latest version of the combustion-based CO₂ emissions data provided by Lee (2008) for all GTAP sectors and regions. It is worth mentioning that we introduced some adjustments to specific sectors and regions where emissions were not consistent with data provided by the main international energy agencies (EIA-DOE and IEA). Since CO₂ emissions data are assigned to each region/sector on the basis of energy input volumes and emission intensity factors, we analysed country/sector specific data in order to understand which factors were driving these distortions the most. We found that for some sectors and regions the emission intensity factors were indeed much higher than the average leading to a substantial overestimation of the corresponding emissions reported in the official IEA data on CO₂ emissions from fossil fuels combustion. In order to reduce this bias, we replaced the emission

⁴ For a comprehensive discussion on substitution elasticities in the energy sector, see Koetse *et al.* (2008), Okagawa and Ban (2008), while Panagarya *et al.* (2001) and Welsch (2008) discuss the role of import demand elasticities in international trade.

intensity factors for those sectors and regions whose values were out of the range $-1/+1$ compared with the official IPCC emission intensity factors (Herold, 2003). On the basis of these new emission intensity factors, we computed adjusted CO₂ emissions, obtaining new values for those sectors/regions characterized by outlier emission factors.

In order to include CO₂ emissions in the GTAP-E model, some preliminary changes had to be made to adapt data to model requirements. Since the most recent CO₂ emissions database do not distinguish between domestic or imported source, we computed these shares as proportional to the volumes of domestic production and imports, respectively. Such a choice is consistent with the methodological assumptions described in Ludena (2007) and Lee (2008) where CO₂ emissions data are calculated from the energy volume data of the GTAP Version 6 database.⁵ It is worth noticing that emissions in our version could not account for all other GHG emissions since they only relate to fossil fuels combustion, thus providing a lower bound estimate of total emissions and abatement targets. Even if the missing emissions constitute a 15% of total GHG, the underestimation is quite homogeneous across regions and sectors with the exception of the agricultural and chemical sectors, thus not influencing the distributive effects of our simulations.

Finally, CO₂ emissions are directly linked to the energy commodities considered in the model such as coal, crude oil, natural gas, refined oil products and gas manufacture and distribution. CO₂ emissions are produced by energy consumption by firms, government and private households. These direct emissions are taxed without discriminating between the source of the energy products. In these sectors, domestic and imported goods are treated alike and there are no grounds for fearing either carbon leakage or competitive disadvantage of national firms. As a consequence, all the CBTs described in Section 3.3 only apply to sectors responsible for ‘indirect emissions’, i.e. emissions deriving from the use of energy commodities as intermediate inputs.

3.2 Model setting and baseline

In order to simulate different scenarios within the Kyoto Protocol policy implementation, an aggregation of 21 sectors and 21 regions was effected (Table 1).

With regard to regional aggregation, we consider a “Post-Kyoto” environment, with 11 Annex I countries/regions featuring country-specific CO₂ reduction commitments. Moreover, we single out the major emerging economies, including Brazil, China and India, since they may be the source of alleged carbon leakage. According to Babiker and Jacoby

⁵ Following Mc Dougall and Golub (2007) and Ludena (2007) we converted emissions data from Gg of CO₂, as they were expressed in Lee (2008), into million tons of carbon.

(1999), for instance, China, India, Brazil plus South Korea and Mexico, account for 60% of global leakage. As far as sectoral aggregation is concerned, in addition to the energy sectors such as coal, crude oil, gas,⁶ refined oil products and electricity, we singled out energy intensive sectors (e.g., cement, paper, steel and aluminium) that are expected to be the main sources of carbon leakage.

Table 1- Regional and Sector aggregation

Regions	Sectors
<i>Bloc Annex I</i>	
EU	Agriculture
USA	Chem., Rubb., Plast.
Australia	Coal
Canada	Crude oil
Japan	Gas
New Zealand	Oil products
Norway	Electricity
Swiss	Metal products
Croatia	Mineral products
Belarus	Paper products
FSU	Electrical equipment
<i>Bloc non-Annex I</i>	
Brazil	Food industry
China	Machinery equipment
India	Motorvehicles
Mexico	Textile and Leather
South Africa	Transport equipment
Energy Exporters	Other Manufacturing
Rest of Africa	Transport
Rest of America	Sea Transport
Rest of Asia	Air Transport
Rest of Europe	Services

Our version of the GTAP-E model, which includes changes in emission intensity factors and substitution elasticities, gives results, in terms of CO₂ emissions, from the baseline 2004 to 2008, which are much more consistent with those provided by international energy agencies such as IEA and EIA-DOE. The improvement obtained is quite substantial since the standard GTAP-E model provides aggregate results that in some cases are at odds with current data. As a consequence, we are confident that our specification is able to provide a more accurate assessment of the potential extent of carbon leakage.⁷

A 2012 baseline was created based on the GTAP 7.1 database and using 2004 data. To this end, we considered a business as a usual scenario for emissions data and considered slow adoption of clean technologies and economic projections to 2012 accounting for IMF and

⁶ The gas sector in the present aggregation includes the sector of natural gas extraction and gas manufacture and distribution.

⁷ Robustness checks for model results to different parameters have been addressed by a sensitivity analysis where standard deviation from results in our version is rather small. More importantly, we have also found that relying on original GTAP 7.1 substitution elasticities, carbon leakage would result into overestimated values, especially due to substitution elasticity between capital and energy in the first nest under the production function.

World Bank information on effective growth rates after the financial and economic crisis. Several steps were necessary to obtain a convincing 2012 baseline. We first updated the database to 2008, assuming population and gross domestic product as reported by the World Bank and IMF data and calibrating the emissions to the most recent IEA CO₂ data (IEA, 2010). The same procedure was adopted to bring the model to 2012. In both cases, while the emissions level in aggregate was correct, its distribution in terms of emissions quota among regions was not satisfactory. As a consequence, in the 2008 baseline, we corrected CO₂ emissions to fit the IEA data (IEA, 2010) while in the 2012 baseline, we calibrated the CO₂ emissions to the IEA projections (IEA, 2010).⁸

As a final remark, we would like to mention that CO₂ emissions in the GTAP-E model, as well as the IEA data, refer to fossil fuels emissions only, excluding all other possible CO₂ equivalent emission sources. As a consequence, we recomputed the 1990 emission levels in order to get consistent CO₂ emission targets in the implementation of Kyoto Protocol commitments.⁹ Even if our ultimate goal is not to provide realistic CO₂ projections but to compare the economic effects of alternative policy scenarios, it is worth emphasizing that Annex I emissions in our baseline are almost identical to those proposed by the IEA (IEA, 2010) and reported in the most recent European Environmental Agency Report (EEA, 2010).

3.3 *Scenario Setting*

Recalling that the rate of carbon leakage is defined as the increase in CO₂ emissions in the rest of the world induced by the domestic reduction measures as a percentage share of the absolute value of the volume of CO₂ reduction obtained by compliant countries (Kuik and Ofkes, 2009), we first check the existence of carbon leakage in a pure Kyoto Protocol scenario, where we impose reduction targets on all Annex I countries with respect to their 1990 emission levels, as if also the United States ratified the Protocol.

We assess the existence of carbon leakage allowing for the possibility of emission trading among Annex I countries (KT scenario) as well as without such a possibility (KNT scenario). Since results show that emission trading is going to be a more efficient policy instrument in terms of compliance costs for abating countries and consequently more convenient in welfare terms at the global level (as explained in details in the results), all the

⁸ Emissions have been swapped with technical progress using a specific closure (Altax) that allows some data preserving the overall consistency of the model to be changed.

⁹ In order to make emission levels in GTAP-E model as consistent as possible with those considered for the Kyoto targets by official IPCC documents, we first calculated the deviation between GTAP-E and IPCC emissions data in 2004 and then we proportionally changed the 1990 IPCC emissions data in order to calculate the effective abatement efforts required by the achievement of the Kyoto Protocol targets.

following simulations assume that the Kyoto Protocol is implemented by allowing for emission trading (Figure 1). When simulating emission targets, some corrective measures should be taken since emission permits potentially supplied by transition economies (the FSU and Belarus in our model) to the carbon market are substantially higher than permits demanded by the other Annex I countries, resulting in a close-to-zero carbon price. Such uncertainties may be included in the so-called ‘hot air’ debate which also addresses the role of the other flexible mechanisms required by the Protocol (World Bank, 2010). In order to avoid these extreme outcomes, we adjusted, albeit partially, the emission targets for Belarus and the FSU. For these countries, emission levels in 2012 represent the reference to which the 0% target scheduled in the Protocol should be applied, rather than the usual 1990 period. This substantially reduces the permits supply in relation to a pure Kyoto Protocol scenario.

The fact that only some countries, namely the ones in Annex I, contribute to a global common goal such as the avoidance of climate change is already quite controversial. The very fact that the efforts made by a group of countries may be undermined, even partially, by the behaviour of others cast serious doubts on the political feasibility of the Kyoto Agreement. Since domestic firms, especially in the energy intensive sectors, are going to be hurt by carbon taxes introduced to meet the Kyoto reduction targets, several governments are considering introducing taxes on imports from countries that have not introduced climate change policies so far.

Figure 1 – Simulation design

Border tax adjustments could be ‘two-way’ if they were also applied to products exported

to Non-Annex countries as is customary in differences in indirect taxes (e.g., the value added tax) between trading partners. However, such an export rebate would provide obvious incentives to keep ‘dirty’ plants operating for export purposes and this would make it even more difficult for the other firms to meet Kyoto commitments. Consequently, all our scenarios are based on ‘one-way’ carbon border tax adjustments (CBTs) regarding all goods that did not pay for the emissions implied by their production (i.e., we focus on sectors that are responsible for ‘indirect’ emissions).

The alternative strategies envisaged in order to cope with carbon leakage usually assume that carbon tax is extended to imported goods from Non-Annex countries either on the basis of the carbon intensity of domestic production or on the basis of the intensity in the exporting country. In order to assess the impacts of these implementation choices, we simulate counterfactual scenarios not related to the current political debate. In these scenarios, carbon tariffs are endogenously determined in order to achieve some predetermined goals such as the elimination of carbon leakage or the preservation of national firms’ competitiveness.

Since we allow for emission trading, CBT scenarios extending the carbon tax to imports (KT-TCCNK and KT-TCC) are based on a single price for carbon emission. However, border taxes are going to differ by sector according to the carbon contents. In the KT-TCCNK scenario, border taxes are based on the carbon content of imported goods whereas in the KT-TCC scenario, they are based on the carbon content of the corresponding domestic production in the importing country. In the latter case, all Non-Annex countries face the same border taxes on their exports to each Annex I country whereas in the former case, all Annex I countries adopt the same policy implying different taxes for the same good according to the country of origin.

The KT-TCCNK scenario is likely to be deemed inconsistent with WTO provisions since it discriminates between Non-Annex countries as well as between domestic and imported products that are going to face different carbon taxes. The KT-TCC scenario avoids these discriminations and it is certainly much more realistic in terms of information requirements, but it should be noted that the *ad valorem* equivalent of the tax differs according to the bilateral flows unit values so that we may well expect exporters of low quality goods to be worse off. CBTs, as a matter of fact, are established in specific terms (i.e., price per ton of emissions associated with the production of each good), and it is well-known that specific tariffs translates into higher *ad valorem* equivalents for goods featuring lower prices.

These scenarios are close to the current political debate, especially in the EU, where a non-distorting trade measure which can be designed as the difference between production

costs before and after tax costs is the same, in absolute terms, in both Annex I countries and elsewhere. A product imported by Annex I countries then faces the same price difference when it enters the market.

By comparing the performances of these two approaches for CBT implementation in terms of efficiency and effectiveness in reducing carbon leakage, we join a large and quickly growing literature. The most innovative part of the paper adds other simulations where carbon tariffs are endogenous to these somewhat standard scenarios, where the carbon tariff is exogenously set according to the tax resulting from the implementation of the Kyoto agreement. To this end, we start from a given goal, either in terms of carbon leakage or competitiveness, and use the model to compute the sector-specific *ad valorem* tariffs that would allow these goals to be reached. The counterfactual sector-specific tariffs are then imposed by Annex I countries on all imports from the Non-Annex countries. Accordingly, these tariff surcharges (since they are levied on top of the existing tariff structure) are uniform across (Annex I) importers and (Non-Annex) exporters although they obviously discriminate between domestic and imported goods.

The first counterfactual scenario (KT-LEAK) targets carbon leakage, and one may think that an obvious goal would be to keep the overall sectoral emissions in the exporting countries constant. It turns out that such a goal is not feasible. In the model, as well as in reality, emissions result from the choices of different agents – governments and families, for instance – whereas exports only concern firms: even if we introduce prohibitive tariffs, we cannot claim to influence overall emissions by only affecting a tiny share of production such as exports. As a consequence, in our simulation, we adopt a closure by swapping the tariff with the emissions by the exporting countries' firms. Such a set-up is already quite insightful: a carbon tariff that eliminates carbon leakage simply does not exist.

As far as the competitiveness scenario is concerned (KT-COMP), we first need to define what is meant by this elusive term. Given that much of the public debate is supposedly about unfair competition in the world markets, we assume that Annex I countries introduce *ad valorem* tariffs so that the share of imports in total production in each sector remains constant.

All the above simulations have been conceived in a non-cooperative setting where Annex I countries adopt unilateral policies in order to cope with the fact that other countries do not act to keep their emissions under control. The final scenario (KT-COOP) simulates the effects of a cooperative solution where Non-Annex countries do not allow their emissions to increase in respect with the 2012 baseline, assuming *a priori* a no-leakage effect, since all Non-Annex countries accept to keep their overall emission levels unchanged. Moreover, the

introduction of emission trading at world level would represent the most efficient way of implementing the Kyoto Agreement. Consequently, even if we do not necessarily consider this scenario a realistic one, we use it as a benchmark in order to assess the relative benefits and costs of the other non-cooperative scenarios.

4. Empirical Results

We first compare the implementation of the Kyoto agreement with and without an emission trading scheme (KT and KNT scenarios). Results reported in Table 2 reveal that, when emission trading is allowed, there is a substantial reallocation in emission reductions. In particular, the United States reduce less with respect to their emissions quota whereas the European Union (EU) reduces more. This result is consistent with the expected higher allocative efficiency of market-based instruments since larger abatement efforts are associated with countries with lower marginal abatement costs, clearly evident from the comparison between the average domestic carbon tax level in the KNT scenario (39.16 \$ per tCO₂) and the equilibrium price for emission permits in the KT scenario (22.92 \$ per tCO₂). This result is hardly surprising if we consider that the EU includes 12 new member states which are characterized by substantially lower marginal abatement costs and less stringent abatement constraints. The combination of these two elements explains why for the EU as a whole it is more convenient to reduce emissions below the Kyoto target, selling emission permits in the international market. The other potential seller is obviously the Former Soviet Union (FSU), as to be expected according to the well-known “hot air” debate (Zhang, 2000, 2001).¹⁰

Both simulations generate carbon leakage, but in the KT scenario, the leakage rate is higher than in the no trade scenario. We can explain this result by considering that leakage is mainly related to a substitution effect in CGE models as emphasized by Gerlagh and Kuik (2007): due to the reduction in fossil fuel consumption, international prices for energy commodities decrease thus stimulating demand from non-compliant countries. When emissions trading is allowed, such a decrease is larger: for instance, the decrease in the average fossil fuel price in the KNT (-4.19) and KT (-4.86) scenarios. The higher allocative

¹⁰ It is worth noticing that in the KNT scenario Belarus and FSU have a zero change constraint to emissions level, in order to reduce the potential dimension of a hot air event. As a control, when simulating a KNT scenario with no constraints for Belarus and FSU, these two countries behave more consistently with a zero constraint rather than with their potential percentage change in a pure Kyoto setting, corresponding to emissions increase by +0.95% and +1.85% with respect to emissions targets of +73% and +48% for Belarus and FSU, respectively.

efficiency due to the existence of a carbon market is mostly relevant for countries with more demanding targets since these countries can reduce their contribution to global demand to a lesser extent by substituting internal production with imports mainly coming from those non-compliant countries.

At country level, the Non-Annex countries most responsible for carbon leakage in absolute terms are represented by South Africa, Rest of Europe and Energy exporters countries,¹¹ and – to a lesser extent – Brazil, India and China.¹²

Notes: a Average Carbon Tax for Annex I is computed as a weighted average of national carbon tax rates

b The price of permits related to the aggregate Annex I corresponds to the equilibrium international market price

It is worth mention that our results are broadly consistent with previous findings, such as, for instance, in Elliot *et al.* (2010b), where the percentage change in emissions associated to a carbon tax of around 23 US\$ per ton of CO2 is in the range of 5-6%, which corresponds to our 5.66% world emission reduction in the KT scenario.

Turning to the welfare effects (Table 3), it is worth noticing that there are large

¹¹ The Energy exporter group represents countries in which energy resources represent the major asset in export flows, as defined by IEA Energy Balances. When Annex I countries apply some abatement strategies, the fossil fuels demand at world level decreases, thus inducing Energy exporters to shift their production structure towards energy intensive industries and explaining their role in producing carbon leakage.

¹² It is worth mentioning that these are very preliminary results since we have not envisaged minimum emission reductions commitments in Annex I countries and the emission-trading scheme does not include any sector constraints.

discrepancies in single welfare components when comparing the domestic carbon tax scenario (KNT) with the existence of an emission trading scheme (KT), since two prevailing effects may be detected.

For countries which are net buyers of carbon permits, there is a substantial improvement in the allocative efficiency loss since energy intensive goods may continue to be produced. In other words, the domestic efforts to reduce fossil fuel consumption in a pure domestic policy scenario would force the economic system to make heavy structural adjustments in the production specialization pattern by relocating production factors across sectors. Net buyers pay the permit price for having the possibility to reduce the adjustments required by the implementation of the Kyoto Protocol whereas the opposite is true for net sellers that are compensated, at least partially, for the larger adjustments through the emission trading revenue.

Source: our elaborations on model results

Babiker *et al.* (2004) find that direct gains from trading permits may be outweighed by “indirect costs” due to pre-existing distortions and market imperfections. In particular, two channels can be traced: an efficiency cost effect of IET (namely an allocative efficiency effect) due to the interaction between carbon taxation and pre-existing taxes and a terms of trade effect if the policy affects international prices, even in the absence of other distortions. According to our results, the allocative efficiency effect seems to have the upper hand.

Since carbon leakage is larger in the KT scenario, from here on, we assume that Annex I countries can trade carbon dioxide emission permits as established in the Kyoto Protocol even if such a mechanism has not yet been implemented. In Figure 2 we combine some results of the KT scenario for the EU and the US by combining changes in the domestic output and changes in imports coming from the Non-Annex group at sector level compared

with values in the 2012 baseline. The fact that most observations stand in the left-hand upper quadrant confirms that reductions in domestic production are often compensated for by a surge in imports from non-abating countries. Since these sectors are also chiefly responsible for carbon leakage (metal products, chemicals, mineral products), this figure clearly shows the relocation of production from Annex I to Non-Annex countries highlighting the linkage between environmental and competitiveness concerns.

Figure 2 – Competitiveness effects for EU and the US in the KT scenario compared with baseline 2012

Source: our elaborations on model results

Let us now turn to the “non-cooperative” scenarios where Non-Annex countries do not keep their emissions under control and Annex I countries react by adopting unilateral policies. We first compare the results of the two scenarios in which carbon tariffs are based on permits equilibrium price for carbon emissions aiming at (re-) establishing a level playing field. In the KT-TCCNK scenario, border taxes are based on the carbon content of imported goods whereas in the KT-TCC scenario, they are based on the carbon content of the corresponding domestic production in the importing country. In the latter scenario, the nominal border tax (expressed in \$/ton) is uniform across sectors and (Non-Annex) exporters while in the first case, the carbon tariff is going to be homogeneous across (Annex I) importers but heterogeneous across sectors and exporters and this will raise further doubts as to its consistency with WTO rules. Table 4 summarizes results in terms of carbon dioxide emissions and welfare changes for these two scenarios.

It is worth noting that the distribution of emission reductions across Annex I countries hardly changes by applying an exogenous CBT. Conversely, the introduction of tariffs strongly affects the geographical distribution of carbon leakage. In particular, the KT-

TCCNK scenario, where the carbon content is related to the exporting countries, reveals a larger impact in terms of leakage reduction, especially for Energy exporters, South Africa, China and India. In any case, the effectiveness of such unilateral policies seems to be rather small since, although carbon leakage is uniformly reduced across all Non-Annex countries, it still remains positive.

This result is hardly surprising if we look at the share of emissions related to exports by Non-Annex towards Annex I countries (Table 5). The first column includes the amount of emissions associated with exports for each Non-Annex countries to the Annex-I group in the KT scenario. If we compare these figures with the total amount of emissions produced by firms in non-compliant countries (the second column), the share of emissions influenced by the CBT is rather low (fourth column) compared with the share on total emissions (last column). In terms of welfare, CBTs improve the terms of trade for Annex I countries while Non-Annex countries register a corresponding loss, resulting in a pure redistribution of unilateral climate change policies costs, without substantial gains in environmental terms.

When we develop a comparison of domestic output and imports from Non-Annex, considering now the results in the KT scenario as a baseline, Figure 3 shows that EU and US domestic production is hardly affected by the CBT when the domestic carbon content is considered (KT-TCC). On the other hand, both countries take advantage of the larger import reductions due to the higher tariffs justified by higher carbon content of Non-Annex countries (KT-TCCNK), especially in energy intensive sectors (see Table 7 for a comparison of tariffs in *ad valorem* terms).

Figure 3 – Competitiveness effects for KT-TCC and KT-TCCNK (EU and US)

Source: our elaborations on model results

In the second set of scenarios, carbon tariffs are endogenously determined in order to keep the overall production emissions in Non-Annex countries (scenario KT-LEAK) and the share of imports in total production in Annex I countries (scenario KT-COMP) unchanged. The KT-LEAK scenario guarantees the lowest rate of carbon leakage, although it should be noted that the problem is only halved since, for the reasons explained in Section 3.3, it cannot be eliminated. In particular, some countries, such as China, India, South Africa and

Rest of Europe, substantially reduce their emissions, and the contraction of their industrial sector is associated with high welfare losses. In this respect, the higher tariffs of this scenario also lead to very large terms of trade gains for Annex I countries. On the other hand, the KT-COMP scenario, even if not explicitly focused on carbon leakage, still leads to a reduction which can be compared with those in the exogenous CBTs scenarios and the same is true for the welfare impacts (see Table 6 for a comparison of these two scenarios).

Looking at the relationship between output and import changes in the EU and the US, Figure 4 shows that the KT-LEAK scenario features larger reductions not only for imports, but also for domestic supply. It is also worth noting that in the KT-COMP scenario, imports decrease only for some energy-intensive sectors and even increase in other cases, especially in the EU market.

Figure 4 – Competitiveness effects for KT-LEAK and KT-COMP (EU and US)

Source: our elaborations on model results

If we look at the comparison between *ad valorem* carbon tariffs for alternative scenarios shown in Table 7, the most striking feature is that the carbon tariffs needed to significantly reduce the carbon leakage problem (scenario KT-LEAK) are much higher than those currently discussed in the political debate (KT-TCC and KT-TCCNK scenarios). It is interesting to note that tariffs aimed at keeping the share of imports from Non-Annex countries constant present some spikes among the energy-intensive sectors. In the KT-TCC and KT-TCCNK scenarios, tariffs are increasing in sectoral carbon contents. With regard to Non-Annex countries and the variance of the tariffs they face, KT-TCCNK and KT-LEAK scenarios are characterized by higher variances in all sectors, and this explains the larger costs arising for Non-Annex countries in these scenarios.

Table 7 – *Ad valorem* carbon tariffs for alternative scenarios*

	KT-TCC	KT-TCCNK	KT-LEAK	KT-COMP

From the Annex I countries point of view, in Table 8 we compare the change in the Revealed Comparative Advantages (RCA) index (Balassa, 1965) implied by the different scenarios. Comparing Tables 6 and 8, an interesting pattern emerges: the lowest protection scenario (KT-TCC) turns out to be the most effective in improving export competitiveness since it is associated with the higher number of positive RCA changes. This confirms that levying high tariffs on intermediate goods has a significantly negative impact on production costs.

Finally, we simulate a cooperative scenario in order to obtain a benchmark for comparison with the other results (Table 9). The cooperative scenario solves (by definition) the carbon leakage problem since Non-Annex countries are committed to keeping their emissions constant in relation to the 2012 baseline. Moreover, in this scenario, we also register a much higher global emission reduction since all countries participate in emission trading and Non-Annex countries have lower abatement costs. In line with previous contributions (Veenendaal and Manders, 2008), our findings confirm that for compliant countries, imposing a CBT is welfare improving with respect to a IET scenario with no carbon tariffs, but welfare gains are rather small, as acknowledged by McKibbin and Wilcoxon (2008), with the exception of the KT-LEAK scenario where terms of trade play a major role.

Table 9 – Comparing results with a Cooperative solution*

	KT-TCC	KT-TCCNK	KT-LEAK	KT-COMP	KT-COOP
CO2 reduction (%)	-5.70	-5.82	-6.09	-5.80	-6.54
Leakage rate (%)	12.91	11.09	6.95	11.43	0.00
CO2 Permits price (US\$ per ton of CO2)	23.15	23.31	24.60	23.17	8.44
Welfare change (million US\$)	-54,235	-55,435	-100,617	-56,074	-20,952

Source: our elaborations on model results

Note: * all figures for CO2 reduction and welfare effects refer to a global effect at the world level

Looking at welfare changes for the world as a whole, our results clearly show that global welfare decreases when CBTs are introduced, as to be expected, due to the negative impacts on allocative efficiency (Table 10).

Table 10 – Welfare decomposition for all countries for the COOP scenario

	Welfare change	ETS permits revenue	Allocative efficiency effect	Terms of trade effect	Investment- saving effect

The cooperative scenario would constitute the best solution since welfare changes, although still negative, are more than halved with respect to the Kyoto scenario with emission trading (KT) and almost five times smaller than the scenario designed to partially eliminate the carbon leakage through unilateral policies (KT-LEAK). Looking at the carbon emission permits price sheds some more light on CBT effects. As a matter of fact, all scenarios featuring CBTs lead to an increase, albeit rather small, in this price. CBTs protect the domestic production of carbon intensive sectors, and this leads to more stringent climate policies to obtain a given emission target, thus resulting in higher emission prices and larger welfare losses.

The distribution of welfare changes in the cooperative solution between Annex I and Non-Annex countries reveals that in relation to the KT scenario, Annex I countries significantly reduce their allocative efficiency losses: the price for that is the cost of the emission permits they need to buy on the market (Table 10). Non-Annex countries face opposite effects since they lose in terms of allocative efficiency but they gain as net sellers on the carbon market. More importantly, allocative efficiency gains (i.e., reduced losses) for Annex I countries are much larger than the allocative efficiency losses for Non-Annex countries.

5. Conclusions

In this paper we propose alternative border tax adjustments for dealing with carbon leakage. We simulate different scenarios to gain a better understanding of to what extent a border tax is effective in reducing the leakage rate, and if major differences emerge when alternative CBTs are modelled. More specifically, we are interested in investigating the real impact in terms of leakage reduction and to what extent such trade policies are also a valid instrument for protecting the economic competitiveness of compliant countries in the international market.

The CGE model adopted is a modified version of the GTAP-E featuring several improvements over the standard version. With regard to the dataset, we introduce updated estimates of the substitution elasticities in the energy composite nests and we provide a more accurate calibration of CO₂ emissions with respect to both historical data and IEA projections. We work on a realistic 2012 baseline, accounting for the economic crisis as well as the climate policies already implemented by some Annex I countries.

Our results confirm that the effectiveness of CBTs in reducing carbon leakage is limited and that they could even be damaging in terms of competitiveness. Moreover, border tariff adjustment compatibility with WTO-rules is still a moot point and justifying them by climate concerns could open the way to a proliferation of trade measures dealing with other areas where the competitive playing field is viewed as uneven (Atkinson *et al.*, 2010). Border trade measures might contravene WTO's Article I on most-favoured nation treatment. The question is whether tons of carbon from domestic or international sources should be treated in the same way and whether a relevant parameter should be considered to decide whether two goods are subject to similar treatment. On the other hand, based on Article XX of the WTO dealing with environmental issues, the absence of a carbon policy in non-abating countries could be considered an implicit production and export subsidy by abating countries (Manders and Veenendaal, 2008; Dong and Whalley, 2008).

In our analysis we also provide a comparison with a global cooperative scenario where all countries contribute to reducing GHG emissions. In the cooperative scenario all major greenhouse gas emitting countries such as US, China and India participate in emission reduction efforts. Non-Annex countries pledge to maintain their current emission levels and they play a relevant role in the attainment of emission reduction target of Annex I countries, by participating in emission trading and offering cheap abatement opportunities. Our results suggest that the cooperative scenario would be preferable both in terms of welfare impacts and efficiency in emission reductions. We show that the cooperative solution is welfare

improving with respect to all CBT forms, while gaining efficacy in CO₂ reduction. This last point suggests that the bargaining power exerted by Annex I countries in the Post-Kyoto agreement should be directed towards a global solution rather than towards short-sighted solutions in which a domestically-oriented point of view prevails which loses effectiveness as well as economic convenience.
